But the great point to secure, if not a bony union, is a ligamentous union as short as possible by the simplest and safest means.

I cannot even mention in a clinical lecture the names of all the machines used to accomplish this end. I will simply say that some are useless, others dangerous, while many, especially those which act on the principle of a figure-of-eight bandage, are very useful.

Let me first say that I have had the patient placed upon a fracture-bed; that the limb is to be extended and elevated, and the fragments coaptated. The method of retention which I prefer is not altogether a new treatment, for I brought it to the notice of the medical profession in a paper published in the *Medical Examiner* of January, 1854, giving cases so treated by me at the Pennsylvania Hospital.

The dressing is often alluded to by writers and teachers in a general manner, but the mode in which I apply it differs somewhat from that described in my paper.

The apparatus consists merely of a back-splint, strips of adhesive plaster three-fourths of a yard long and one inch wide, and two or three rollers.

The back-splint should be made of half-inch plank, and should reach from the middle of the thigh to the middle of the leg, at the same time corresponding to the thickness of the limb. It should be padded on its upper surface in the middle, to fill up very fully the popliteal hollow. After it is applied to the back of the knee it can be retained at first

by a strap or two circularly applied at each extremity. Then the accurate coaptation of the fragments is to be effected by applying the middle of the loop of a plaster-strip immediately below the lower fragment, and, drawing the extremities upward and obliquely, fastening them to the under surface of the splint. The wooden surface secures a firm adhesion, much more so than if the ends of the strips were fastened to the skin. After the lower fragment is fixed, the upper can be approximated to it in the same manner by loops successively applied, and the extremities drawn very obliquely to the lower and under surface of the splint. Then a roller is to be applied from the foot upwards, extending beyond the middle of the thigh so as to compress the muscles and prevent the extensor from contracting. Now we will place the limb upon an inclined plane, and elevate it as much as possible, so as to approximate the origin and insertion of the rectus muscle. In a few days this swelling will subside and the dressings be re-applied, and thus the fragments can be still more closely approximated, and the probability of a short ligament considerably enhanced.

Thus the patient is to lie for at least six weeks, although the posture can be changed and still the same effect be produced by raising him to a sitting posture whilst lowering his limb. Six weeks more will be required to render the union sufficiently firm to be used. It is from a disregard of this knowledge—that it takes as long a time to mend a patella as it does to mend a fractured thigh—that unsatisfactory results are so often obtained. And, although the limb be kept extended and fixed for three months, ankylosis will not occur; but some stiffness will remain for a long time, and frictions and partial flexions will have to be constantly maintained until the gradual use of the limb is secured.

By these means this man will have a useful limb, and if the ligament is one-third, one-half, or even three-fourths of an inch in length, he will walk perfectly well; if it is longer than this he will experience some difficulty in going up-stairs.

ORIGINAL COMMUNICATIONS.

OLD AND NEW DOGMATISM.

BY HENRY HARTSHORNE, M.D.

I HAVE read with much interest, in the *Philadelphia Medical Times*, two papers by Dr. B. Lee, referring to croup and diphtheria. Upon some portions of the second (June 5, 1875), entitled "The Moloch of Tradition," I desire to comment briefly.

The question of the identity or non-identity in nature of all serious cases of "acute faucial,"* laryngeal, and tracheal disease is very important in pathology; it is important, practically, at least, to those whose therapeutics do not limit them to the employment of "antizymotics and tonics, and the avoidance of all depressant measures," in certain cases of what not only tradition, but careful obser-

vation also, shows to have the character of inflammatory disease.

Without leisure to argue this question at length, I would suggest that, to use Dr. Lee's figure, there are some iron-clads which can resist even "heavy ordnance." While my own convictions on the subject have been chiefly formed by the study of cases in practice, sufficient in number to afford ample material for an individual conclusion, we will not need to look far to find examples of authority, recent, and, in a safe sense, "progressive," to set against that of the distinguished English physician cited by Dr. Lee. Such examples are those of Niemeyer (though deceased, still influential), Oppolzer, Letzerich, C. West, Flint, Lewis Smith, and Fordyce Barker. All of these have maintained distinctly the specific nature of diphtheria, as another affection from acute non-specific laryngo-tracheal inflammation, with or without pseudo-membrane; the existence of membrane in the greatest number of fatal cases, the last of which is, however (not a *tradition*, but), a long-established *fact*. I know of no better evidence sustaining the distinct existence of these two diseases than that presented by some statistics quoted in the work of Meigs and Pepper; especially satisfactory, because, in that work, the identity of all cases of membranous croup with diphtheria is maintained. The statistical facts to which I thus refer are these: in the mortality lists of Philadelphia, diphtheria does not appear before 1860; while croup had occupied a place of importance from time immemorial. In 1860, diphtheria was credited with the large number of 307 deaths. If a mere change of nomenclature or diagnosis had taken place, these deaths would simply have *substituted* in the lists those from croup. But, instead of this, the number of deaths reported from croup was in this and the succeeding years somewhat (though not largely) greater than before. The figures were as follows:

	Croup.	Diphtheria.
1855 . . .	265	
1856 . . .	268	
1857 . . .	256	
1858 . . .	292	
1859 . . .	312	
1860 . . .	354 . . .	307
1861 . . .	304 . . .	502
1862 . . .	258 . . .	325
1863 . . .	444 . . .	434
1864 . . .	455 . . .	357

Thus, the whole number of deaths by croup from 1860 to 1864 inclusive was 422 more than during the previous five years. This was no greater increase than might be expected from the continuous increase of population. But, during the time from 1860 to 1864, the deaths from diphtheria in addition to those from croup amounted to 1925.

It appears to me impossible for any one engaged in practice in Philadelphia during the period named, from 1855 to 1864, not to have observed that a new disease was introduced among us. Croup we had known always; its false membrane had not only been figured in all the books and preserved in pathological collections, but it had been met with in our patients. But diphtheria, although no doubt

* Dr. B. Lee's expression.

described in some (at that time) almost forgotten medical histories of previous epidemics at home and abroad, was yet, then, with us new. I remember to have obtained the aid, in consultation, of the late Dr. William Pepper, in the treatment of the first case of diphtheria which he saw; it was in West Philadelphia, at a house in which four cases successively occurred, two being fatal. Such facts impress one in a manner not to be forgotten.

Among the authorities quoted by Dr. Lee in his second article, the most eminent is Sir William Jenner. This is a change of opinion on his part; and I doubt whether all careful readers will consider that his reasons given for it are quite sufficient. He evidently is in doubt about it himself, using such words as these: "I am inclined now to this belief. . . . I say I am inclined to this belief. I am not sure that it is true," etc. This caution may be commended. My present purpose is, indeed, not more to put in a plea on behalf of a pathological opinion of whose correctness and importance I am convinced, than to protest against dogmatism, *new or old*, in matters of medical science. If there be, indeed, a "Moloch of tradition," there is also a Belial of recent authority, which may be as blindly worshipped. We have had in our age too much of a tendency to regard everything as false or "obsolete" which was known ten or twenty years ago; and everything reliable in the serious business of dealing with disease, which is "advanced" or "progressive" in its omissions or commissions. "Indiscriminate phlebotomy" (if it ever existed) is a thing of the past, which can never be revived. If there be, in the use of this phrase in the article to which I have been referring, an allusion to a vigorous address before the late session of the American Medical Association, delivered by a distinguished surgeon, the latter is not likely to be appalled by the vision conjured up of a "gory altar." Let us by all means allow literature to have its own exclusive use of such rhetorical images. The calm vision of science is not aided but clouded by their obtrusion into her sphere.

REMARKABLE CASE OF GALL-STONE.

BY J. V. SHOEMAKER, M.D.

DR. J. F. BIRD was called early in the spring of 1874 to Mrs. S., who had already passed a number of gall-stones. The characteristic pains had been experienced during the passage of these stones. Under treatment the patient became somewhat relieved, but very soon a rapid emaciation commenced, and, although the appetite was good, there was no nutrition. A large movable tumor soon appeared immediately in connection with the *liver*, which was considered by a consulting physician to be due to *cancer*.

The patient died of extreme exhaustion the 29th day of July, and at the post-mortem examination the gall-bladder was found to be perfectly impacted with gall-stones, varying in size from a small partridge-shot to a garden-pea. They numbered nine-

teen hundred and forty. There was not a single vestige of biliary secretion, even the gall-bladder itself being colorless. The duct was considerably enlarged at its hepatic extremity in consequence of the frequent passage of gall-stones through its calibre. The liver was rather diminutive in size, but not changed materially in structure or color.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. AGNEW, MAY 19.

Reported by DR. J. WILLIAM WHITE.

VARICOCELE.

CASE I.—This patient, a man *æt.* 33, has, as you see, a swelling or enlargement in his scrotum, disappearing when he lies down, and returning when he resumes the erect posture. Now, knowing these two facts about a swelling in this locality, you know that it is either a varicocele or a reducible hernia. The diagnosis between these conditions is so easily made that a mistake is simply inexcusable. Make your patient lie down, wait until the swelling has disappeared, and then place your finger firmly over the internal abdominal ring, retaining it there while he again stands up. If the disease is a hernia the swelling will not re-appear, but if it be varicocele it will speedily return, and rather more quickly than usual, because you are obstructing the spermatic veins and preventing the return of blood from the tumor. Usually, in these cases, I do not advise any operation so long as the tumor gives no special trouble and the testicle shows no disposition to atrophy. Frequent bathing with cold water, and the use of a suspensory, will generally relieve the patients of the pain and weakness in the lumbar region, the feeling of weight and dragging, and the burning sensation of which they usually complain. Sometimes, however, as in the present case, an operation is rendered necessary by the condition of the testicle, as well as for the relief of the painful symptoms. The old plan consisted in laying open a portion of the scrotum and excising the veins; another, in occluding them by pushing a pin underneath, and surrounding them with a ligature externally. This latter was very painful, as the skin was constricted by the ligature.

A much simpler way is one which I will now employ, and by which we can throw around the veins a subcutaneous loop which can be disengaged at any time. The first step is to separate the *vas deferens*, which feels like a piece of wire, from the other constituents of the cord. Having done this, we push it to the rear, and then put a needle through between it and the veins. We then nick the skin slightly, and enter a second needle, double-threaded, carrying it between the veins and the skin. It is then withdrawn. The loop of the thread is then passed under the end of the first needle, while the two free ends are brought down and tied lightly around the other end. We thus have the veins constricted by a loop which can be removed at any time merely by withdrawing the needle. It is usually left in position for about seven days, unless there is much fever with marked constitutional disturbance. Although varicocele sometimes returns, it has not been true in my experience that, as Mr. Symes says, it does so in all or nearly all cases. On the contrary, we may usually look forward with considerable confidence to effecting a permanent cure by this method.

ILIAC ANEURISM.

Case II.—We have here a strong, healthy-looking man, æt. 47, of fair constitution and good family history. He confesses to drinking freely, and we notice that he has the scar of a suppurating bubo in each groin. We also observe on feeling his pulse in the right wrist that he has a very small, atheromatous radial artery which is hardly discernible. Eighteen months ago he tripped and had a slight fall, and ever since has had obscure pains about the pelvis and right thigh, but, until about five months ago, there was no external evidence that he had sustained any injury. Then a tumor made its appearance under Poupart's ligament on the right side, and has since grown to what you see are its present dimensions. It is about four inches in diameter, and extends from the crest of the ilium to the median line. It involves the femoral below Poupart's ligament to the extent of two or two and a half inches, and the external iliac for an indeterminate distance. It has a centrifugal heaving movement, which ceases when I make firm pressure on the abdominal aorta or primitive iliac. On laying my ear over it, I can hear a thrill or bellows-sound. Compression has already been tried with an abdominal tourniquet, the pad of which thrusts the iliac artery against the brim of the pelvis. It was continued for five hours with the aid of morphia and ether, and at the time of removal there seemed to be some solidification, but the pulsation did not cease entirely, and has since returned. We propose to repeat this trial, as in such cases compression should certainly be very thoroughly employed.

Ligation of such a large vessel as the external iliac is a serious matter. We would have to go far up it, nearly to the bifurcation of the primitive iliac, and then would run the risk of not getting a firm clot and not having the artery entirely occluded. In fact, it is extremely probable that in this case we would have to ligate the common iliac, an operation which has been attended with a fearful mortality,—29 out of 39 cases having died. Iliac aneurism is of very rare occurrence compared with other forms, only 9 cases having been reported to 551 cases of aneurism of other vessels. In two of these cases the primitive iliac was tied: one died and one recovered. In four the vessel was sound enough to admit of the application of the ligature to the external iliac. All of these recovered. In one case the abdominal aorta and the distal extremity of the femoral were ligated, but this proved fatal in a few hours. In three cases compression was used, and these all recovered.

Hence, as in this case we have every reason to believe there is a diseased arterial system, and as we would probably be compelled to tie the common iliac, we will give compression an extremely thorough trial.

(This case was subsequently entirely cured by compression of the abdominal aorta with an abdominal tourniquet, and up to the present time no return of the pulsation has taken place.)

ENCEPHALOID TUMOR OF NARES AND ANTRUM.

Case III.—You will notice the peculiar physiognomy of this boy, æt. 8, who is suffering from encephaloid growth situated in the nasal cavity and pharynx and encroaching upon the antrum. The cheek and eye of one side are pushed out and rendered prominent; the superficial veins are conspicuous, owing to the pressure of the tumor on the deep veins; the respiration is stertorous and difficult, from the involvement of the pharynx and soft palate. This tumor has grown to its present size within a month. We will remove it with the intention of giving present relief, not with the hope of curing it permanently.

(The tumor was removed in fragments with forceps, as the base was too broad to be encircled with a loop. It was found to be encephaloid.)

TUMOR IN PAROTID REGION.

Case IV.—This patient, a female, æt. 25, is suffering from a swelling, which has followed a blow received eight months ago, and which has grown slowly ever since. Although it does not occupy the parotid region on the neck, it exactly conforms to it on the face, being bounded above by the zygoma, behind by the cartilage of the ear, and in front by the masseter muscle, this space corresponding to the limits of the parotid fascia. It may be that there is a low inflammation going on which will result in an abscess; but when I see a slow growth, with a sense of elasticity, occurring on the side of the face over the parotid region, I remember that that gland sometimes assumes malignant action, and am, therefore, cautious in my prognosis. In this case it cannot positively be asserted that either view is correct. We will simply order a lotion of equal parts of laudanum and iodine, and will wait.

JEFFERSON MEDICAL COLLEGE.

SURGICAL CLINIC OF PROF. S. D. GROSS.

Reported by F. H. FENTON.

VARICOCELE.

C. R., æt. 19 years. This patient is complaining of an enlargement on the left side of the scrotum, the latter being well marked by ridges, and the testicle is felt lying at the bottom. It is simply an immense tumor: larger than any I have ever hitherto seen in one so young. This affection evidently is a varicocele. It is most common between the ages of fourteen and twenty years, though I have known it to happen as early as at the age of eleven years. I propose to ligate the enlarged and distended veins subcutaneously, first taking care to separate the vas deferens from the mass, as any injury to it would result in a wasting away of the testicle. As I grasp the tumor it feels like a mass of earth-worms, and the vas deferens gives us the sensation of a whip-cord between the fingers; and for this reason the separation from the veins is very easy. Now, having separated the vas deferens from the veins, and grasping it between my thumb and finger, I carefully pass a needle, armed with a silver ligature, behind it, directly passing through the walls of the scrotum, and bringing it out on the other side. I then compel my needle to retrace its steps, taking care to pass my instrument in front of the veins, thus making but one puncture on either side. Then, drawing my ligature through, I twist the ends of it over a perforated button. In three days I shall untwist the wire and tighten it again. The treatment will be of an antiphlogistic character. The patient will be kept in bed, on a light diet, with the scrotum suspended and kept constantly wet with cold water and also a solution of Goulard's extract and laudanum. I prefer to operate, as you observe I have done here, with the patient in the standing position.

TRANSLATIONS.

POISONING BY CHLORAL—STRYCHNIA AS AN ANTIDOTE—RECOVERY.—Dr. E. Levinstein reports the following case (*Centralbl. für Med. Wissen.*, 1875, No. 17).

A man who had taken about six drachms of chloral was found half an hour afterwards in deep sleep, but without threatening symptoms. A little later, however, tumultuous action of the heart, with difficult and interrupted respiration, set in; and later still the action of the heart became greatly enfeebled, so that, even in

the carotids, scarcely any pulse was discernible. The pupils were greatly contracted, and the temperature sank to 91.2°.

Artificial respiration, by passive movement and faradization, proving of no avail, one-twenty-second of a grain of strychnia was administered hypodermically. Convulsive movements of the muscles almost immediately ensued, and soon after trismus; the cardiac movements again became perceptible, the pupils dilated, and the temperature rose to 92°. Shortly after, the former threatening symptoms appearing once more, a second injection of strychnia, to the amount of one-thirty-second of a grain, was administered. The effect of this was similar to that of the first, the temperature rising to normal; but artificial respiration had to be kept up for eight hours. Trismus and tetanic spasm remained for fourteen hours after the second injection; but at the end of thirty-two hours the patient awoke feeling fresh and well. No gastritis followed the ingestion of the chloral, probably because the patient's stomach contained food at the time. X.

LOSS OF HORIZONTAL MOVEMENT OF THE EYES—SOFTENING OF THE CEREBELLUM.—At a recent meeting of the Société de Chirurgie (*Le Mouvement Méd.*, May 22), M. Parras stated that lesions of the cerebellum might influence the associated movements of the two eyes, reading notes of the following case in illustration. X., aged 39 years, was admitted to the Lariboisière, March 23, 1875, complaining of gradual loss of vision, extending over two years, without any loss of consciousness at any time. His face was pale, the eyes haggard, pupils somewhat enlarged, insensible to light; acuteness of vision reduced; rather more on the left than on the right. Ophthalmoscopic examination showed hypermetropic structure of the eyes, large physiological excavation of the papillæ, veins large, gorged with blood, arteries small, all else physiological on both sides.

All horizontal movement of the eyes was wanting, both alone and when both were attempted to be moved together. Movements of elevation and depression could still be performed, but to an impaired degree on the left side. The day after his entrance into the hospital, the patient was agitated, suffered severe pains; the right side of the body was seized with cramps; cutaneous sensibility was preserved; replies sluggish. Death ensued in the evening.

Post-mortem examination showed an average amount of fluid in the ventricles, adherence of the meninges about the left cerebellar fossa. The cortical layer of the left lateral lobe of the cerebellum showed gray softening as far as the white substance, which was healthy. The other portions of the cerebellum and cerebrum were also in good condition. Only the cortical substance of the inferior vermiform process was affected with a certain degree of softening.

In fact, this was a lesion limited to a certain portion of the gray substance of the cerebellum, to which was due in this particular case loss of horizontal movement of the eyes. X.

CONTRACTION OF THE TRAPEZIUS, SIMULATING DEVIATION OF THE VERTEBRAL COLUMN, TERMINATING IN CURE.—I. C. T. Pravaz (*Centralbl. f. Chirurgie*, from *Gaz. Hebdom.*, 1874, No. 30) records the following case:

A young girl of fourteen was affected, after some severe mental disturbance, by a deviation of the spine, the bending of the vertebral column progressing gradually for four months, until scoliosis to a marked degree was attained. The dorsal vertebræ were most severely affected, the convexity above being to the right, with compensating deviation below. The upper and inner angle of the scapula was raised, the lower angle drawn strongly off. The upper part of the right tra-

pezium was hard, and painful to pressure. By faradization of the anterior serratus magnus the scapula could be brought into position again. Galvanization of the trapezius, douches, massage, all were of no avail. Hypodermic injections of a one per cent. solution of atropia to the extent of two to four drops twice a week were then ordered. No effect was felt from these until the dose had been increased to six drops, which brought on general toxic symptoms. The spinal deviation began to amend from this time, and eventually the case ended in entire recovery.

Dr. Pravaz adds short notes of two similar cases coming under his care, both of which were successfully treated by atropia-injections. X.

ANTHELMINTIC ACTION OF KAMEELA.—M. Blondeau (*Bull. Gén. de Thérap.*, May 15) has employed the tincture of kameela with success in cases of tænia. He gave, in one case, f3vj tincture of kameela in infusion of sage, divided into three doses and taken at intervals of an hour,—at nine, ten, and eleven in the morning. At one o'clock in the afternoon, without having experienced the least colic, the patient voided an enormous tænia, the head of which was unfortunately missing.

This anthelmintic possesses, according to M. Davaine, who also advocates its use, the following advantages: it is not disagreeable to take, it does not cause colic, and it need not be associated with a purgative.

(NOTE.—Kameela is obtained from the capsules of one of the Euphorbiaceæ,—the *Rottlera tinctoria*. It is a red powder used in dyeing silk. Its use as an anthelmintic has been suggested by Hunsby. Anderson, who has also employed the tincture, has never gone beyond the dose of f3iiss.) X.

MIXED INJECTIONS OF MORPHIA AND ATROPIA IN THE DYSPNŒA OF PHTHISICAL PATIENTS.—Every one who has had charge of consumptive patients, says Dr. Forcauld, is struck by the powerlessness of therapeutics in presence of those attacks of dyspnœa which render the last moments of these unfortunates so painful.

Struck with this fact, Dr. F. has made numerous experiments with narcotic injections upon patients under his charge, which he details at some length in *Le Mouvement Médical*, May 22. His conclusions are as follows:

1. The mixed injection (equal parts solution of muriate of morphia 1-30 and sulphate of atropia 1-100) presents all the advantages of the injection of sulphate of atropia, without its inconveniences.

2. Six drops of the mixed injection give, as against suffocation, as good results as fifteen drops of solution of muriate of morphia.

3. As after the employment of either the morphia or the atropia alone, there is a diminution in the number of respiratory movements, in the temperature, and in the pulse. X.

THE EFFECT OF REPEATED VENESECTION UPON THE GASES OF THE BLOOD.—The following are the results of a series of experiments instituted to determine the influence of the velocity and quantity of blood upon animal combustion, by Dr. Dittmar Finkler (*Archiv für Physiologie*).

With the increasing loss of blood the oxygen of the venous blood decreases in a manner that is surprisingly rapid; whilst the carbonic acid shows only an unimportant rise.

The consumption of oxygen is absolutely independent within certain limits of the velocity of the blood-current; this law seems also applicable to the formation of carbonic acid.

A result of great interest from his experiments was that after a venesection amounting to one-third of the

whole quantity of blood, no diminution whatever of the consumption of oxygen took place; and the formation of carbonic acid was apparently just as little affected, at least in the course of the next hour after the experiment. This is renewed and unmistakable evidence, in conformity with Pflüger's law, that the consumers of oxygen are to be looked for in the tissues. W.

PHYSIOLOGICAL STUDIES ON A PATIENT WITH ARTIFICIAL ANUS (Démarquay: *Centralblatt für Chirurgie*, No. 14, 1875).—The patient upon whom these investigations relative to the course of the contents of the intestine were made was a man aged 63 years, in whom an artificial anus opening into the lower part of the small intestine had been established by the sloughing of a strangulated hernia.

When the patient suffered no digestive derangement, a tolerably long time elapsed before the altered food, which was colored with subnitrate of bismuth, made its appearance at the fistulous opening; if, however, there was any irritation of the digestive tract, the altered food was seen at the orifice in twenty minutes.

For the purpose of testing the rapidity of absorption of the mucous membrane of the intestine, one hundred grammes of mucilage containing one gramme of iodine were introduced into the intestine through the fistula. A catheter was passed into the bladder, and after eight minutes both the urine and the saliva were found upon testing to contain iodine. If the solution of iodine was introduced into the stomach, forty minutes elapsed before a characteristic reaction was obtained from the urine; if into the rectum, twenty-five minutes. After an injection into the connective-tissue, iodine was found in the saliva in twenty minutes, and in forty in the urine. Démarquay concludes that the cause of the more rapid absorption from the intestine must be sought in the epithelium, and not in the venous system, since this latter is more plentifully developed in the stomach.

W. A.

FRACTURE OF THE PELVIS, WITH RUPTURE OF THE BLADDER, AND DIAPHRAGMATIC HERNIA OF THE LIVER (G. Jüdel: *Centralblatt für Chirurgie*, No. 14, 1875).—A laborer, aged 35 years, fractured his pelvis by a fall from a great height, and this injury was followed immediately by paralysis of the sphincter ani, and later by that of the sphincter vesicæ. A large bed-sore healed, as did also a perforation of the bladder, and six months after the injury the patient died of repeated attacks of erysipelas.

At the post-mortem examination it was found that there had been a longitudinal fracture of the sacrum, which passed through all the sacral foramina of the right side and extended into the coccyx, which had united with considerable displacement of the fragments. There had also been fractures of the transverse processes of the lumbar vertebrae from the second to the fifth, which had also united; a comminuted fracture of the ascending ramus of the right pubis, and a simple fracture of the descending ramus of the same bone. There was also a diaphragmatic hernia of the liver.

W. A.

PUNCTURE OF STRANGULATED HERNIA (Ollivier: *Centralblatt für Chirurgie*, No. 22, 1875).—A man aged 64 years had an inguinal hernia, which had been strangulated for twenty-four hours, and taxis under chloroform had proved unavailing for the reduction of the tumor. Forty-eight hours after the first symptoms of incarceration a puncture was made, followed by the evacuation of a quantity of brownish serum. The ordinary operation for strangulated hernia was then performed, the gut replaced, and death resulted eight hours later.

The patient in a second case was a woman aged 65 years, who had a large umbilical hernia, which had

been strangulated some hours. Chloroform was not used in her case, owing to the presence of some cardiac lesion. A trocar was thrust into the tumor, and a wine-glassful of serum evacuated, when the hernia was reduced by taxis and the patient made a speedy recovery.

The puncture, to be of use, must be made a short time after the constriction of the intestine occurs, while the elasticity of the coats of the gut still exists; so that, by their contraction upon themselves, the opening made by the trocar may be closed. W. A.

A CASE OF ALMOST ENTIRE ABSENCE OF THE CLAVICLES (O. Kappeler: *Centralblatt für Chirurgie*, No. 22, 1875).—The examination of a girl of 16, who was of small stature but otherwise well developed, showed that both clavicles were almost entirely wanting. On the right side of the sternum there was a rudimentary bone one and one-half centimetres in length, and on the left side one of four centimetres. The patient was able to draw the shoulders so near together that there were but nine centimetres between the heads of the two humeri.

The sterno-cleido-mastoid muscle of one side was absent; but it is of interest to observe that there was no disturbance of function; the patient, for instance, could readily support the trunk upon her hands.

W. A.

THERAPEUTIC NOTES.

GASTRALGIA.—M. Gaillard employs the following formula with success against the element of pain as occurring in dyspeptic gastralgia. He designates it by the name of "white drops."

℞ *Aquæ laurocerasi*, fʒiiss;
Morphiæ acetat., gr. iss.

One or two drops are to be taken on a lump of sugar after meals.

IODOFORM CRAYONS.—The following crayons are recommended by Dr. Leblond in superficial ulcerations of the cervix; they are introduced and kept in position with the aid of cotton wadding and a tampon.

℞ *Pulv. iodoform.*, ʒiiss;
Acaciæ pulv., gr. viii;
Mucilaginis, q. s.

Ft. in pil. mas.

Divide into ten cylinders of equal size, about one and a third inches in length, and dry in the air for twenty-four hours. These cylinders are hard and resistant, and may be divided easily into fragments of any desired length. They should be kept in the dark.

ANTI-SCROFULOUS SYRUP.—

℞ *Potass. iodid.*, ʒi;
Tinct. iodinii, ʒj;
Syrupi gentianæ,
Syrupi quiniæ, āā fʒii.—M.

One or two dessertspoonfuls a day in scrofulous cases, combined with cod-liver-oil, etc.

ANTI-BLENNORRAGIC POTION.—

℞ *Tinct. hyoscyami*, fʒss;
Acid. benzoic., gr. xv;
Mucilaginis, fʒiv.—M.

The potion to be taken in the course of twenty-four hours by patients in whom it is too late to have recourse to the abortive treatment, and where, although the discharge is decidedly purulent and micturition painful, it is too soon to employ balsams. Cooling drinks are to be prescribed at the same time, and also injections of pure water frequently repeated. After some days of this treatment the pain ceases, and it is then proper to begin the administration of copaiba and cubebs.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 26, 1875.

EDITORIAL.

SOME OF THE ATTRACTIONS OF OUR PROFESSION.

SOME years since, when, by invitation from our Board of Health, the smallpox visited us, a certain fashionable parish rang with the praises of a no less fashionable clergyman, because he visited those whom the pestilence had seized. No one ever thought of the doctors, and, indeed, the doctors never thought of themselves, but took, as they always do, the exposure as a matter of course. The members of the profession who have fallen at the post of duty in typhus-wards, in cholera-hospitals, and in pest-stricken cities, as well as amid the clash of battle, are now legion. It is not, however, to chant a pæan to their valor that we desire to-day. We want only to call attention to some lesser dangers in the path of the profession, and to one danger that to some may seem greater than all. There is something worse than death, and such a thing seems to us to be sent, though innocent, shipwrecked in health and an outcast into the world with the brand of sin and licentiousness upon the forehead. Recently the English journals have been a good deal occupied with the discussion of the infection of doctors by syphilitic patients, and some very sad cases related,—one, especially, in which a highly-educated, brilliant, and most correct man became a wanderer, and almost a Pariah, through the action of a virulent infection upon body and mind.

Cases of this character are not so rare as some imagine. A prominent surgeon said, not long

since, in our hearing, that he had seen three within a short time. Quite recently, in London, a surgeon contracted a primary sore on the finger, and, before he suspected its character, he inoculated a patient, who instituted a civil suit. By a strange perversion of justice, the unfortunate doctor was mulcted in heavy damages. As the danger of infection is so real, the suggestion of one of the London journals that physicians when called to doubtful cases of obstetrics should protect their fingers by fine india-rubber stalls seems worthy of attention.

THE annoyance, and sometimes the loss, by mal-practice suits has been sufficiently exemplified from time to time in this country, but it has been reserved for the Lincoln Assizes of England to invent the last means of "torture to a medical man." A Dr. Wood has been put on trial for manslaughter because, forsooth, he did not stay long enough, or administer sufficient brandy to a woman, who, apparently through no fault of his, and unknown to him, was doomed to die when he left her. The doctor was summoned hastily to a Mrs. White, found her suffering from uterine hemorrhage, and delivered her without delay. The woman seemed exhausted, but bore the delivery well, and ten minutes after the doctor left. It appears to be acknowledged that up to his leaving his procedures were proper and were skilfully performed. But the woman sank, and died three hours afterwards. At the post-mortem a uterine rupture was found. It had not given rise during life to any symptoms, or at least certainly had not been suspected. Nevertheless, for leaving, probably under the press of other engagements, ten minutes after the completion of delivery, Dr. Wood may yet serve out his term of years with the common convicts, and go out finally an utterly ruined, broken man. Who would not be a doctor?

NEW JERSEY STATE MEDICAL SOCIETY.

IT may not be known to all of our readers that this Association is the oldest in the United States, the first session having been held at New Brunswick, July 20, 1766, and Dr. McKean elected President. During the Revolutionary War there was a break in the otherwise continuous chain of annual sessions since 1766. The Society was reorganized, or rather revived, in 1781, the same year in which the Massachusetts Medical Society came into being. There was a medical society in this city in 1768, but the oldest association now existent is the College of Physicians, which was founded in 1787. Our State Society was not established until 1848.

No charity appeals more forcibly to the fathers and mothers of little ones than does the Children's Sea-Shore House, with whose objects all our readers are, without doubt, well acquainted. Under the management of Mr. J. S. Whitney, the institution is steadily increasing in usefulness, and during the summer of 1874 afforded the benefits of cool, salt air, with proper attendance and nourishment, to one hundred and eighty children, who would otherwise have languished, and many of them perished, in our by-ways. But what is this among so many? That it may be more, will not our readers call the attention of their rich clients, when leaving for the sea-shore, to this most serviceable of charities?

THE *Irish Hospital Gazette* thinks "it is quite time that those who have the education of the male human animal should by some means drive or hammer it into his dense moral consciousness that his procreative power was not given him solely as a means of amusement, and that women have other functions besides that of ministering to this often morbidly excited appetite." We agree perfectly with this, and also with the sentiment that "the rights of the husband," so called, are often in truth the wrongs of the wife. But then the hammer of Thor would be required to drive this into the head of the ordinary male animal of the species homo.

DR. GEORGE H. BIXBY, of Boston, respectfully solicits from members of the profession in the United States who have performed ovariectomy their experience in brief in regard to pregnancy subsequent to that operation. Answers to the following questions will be gratefully received and duly acknowledged:

Number of cases,	Adhesions,
Age,	Treatment of pedicle,
Social state,	Number of births,
Previous births,	Nature of births,
	Subsequent history.

Address 143 Boylston Street, Boston, Massachusetts.

THERE appears to be some reason for the practice of cremation in the West. Apparently owing to the great scarcity of land, in some places the dead seem to be crowding out—or rather in—the living. In Grand Rapids, according to Prof. Kedzie, a certain street was plague-haunted, and, on investigating the cause, the soil was found to be gravelly and porous, and the wells within twenty feet of the graves. Evidently the families had been drinking the "drippings of death." A case of cannibalism in disguise.

LEADING ARTICLE.

JABORANDI: ITS PHYSIOLOGICAL ACTION.

THIS drug has been employed for a long time in South America, and received its first notice, under the various names of *Jaborandi*, *Jaguarandy*, and *Janguarandi*, from Dr. T. J. H. Langgard in his "Diccionario de Medicina domestica," Rio Janeiro, 1865. It attracted no attention, however, until 1874, when it was brought to Paris by M. Coutinho. Its botanical source is not known, but is believed to be *Pilocarpus pinnatus*,—a member of the rue family. The leaves are oval, elongated, entire, 1.2 to 1.5 inches long, and one-third to one-fourth as broad; their taste is bitter, their odor hay-like. Rabuteau (*L'Union Méd.*, 1874) failed to find in them an alkaloid, and believes that their activity depends upon a bitter principle. Dr. Frerichs asserts (*Berlin. Klin. Woch.*, May, 1875) that the virtues reside solely in the bark and leaves.

When an infusion of from sixty to ninety grains of jaborandi is given to an adult, in about ten minutes the face and neck become deeply flushed, and free perspiration and salivation commence. The sweating and salivation are excessively profuse, and last from three to five hours. There is not rarely nausea, and sometimes even vomiting. After the sweating has ceased, the patient is left more or less exhausted. The nasal and lachrymal secretions are also, at least sometimes, increased under the action of the drug, and M. Gubler has noted diarrhoea, which in the experiments of Ringer and others has not been present.

These effects of jaborandi are in the adult quite constant, although, occasionally, subjects have been found who were not susceptible to the action of the drug, and, very curiously, in Dr. Ringer's experiments children were found to be very unsusceptible, although doses of sixty grains were employed.

Sometimes the salivation is more profuse than the sweating (*Férol, Jour. de Thérap.*, January, 1875), and very frequently it commences before the sweating. During it the mouth is warm, and there is often a feeling of tenseness about the maxillary glands; the saliva contains abundance of salts and of ptialine, as well as a small excess above normal of urea (*Jour. de Thérap.*, vol. iii.). The free salivary secretion appears to be due to a direct action upon the gland or its nerve-peripheries. According to I. N. Langley (*British Med. Jour.*, p. 247), in the frog the mouth and skin, after the exhibition of jaborandi, become covered with a viscid secretion, and in the dog and rabbit there is profuse salivation. In the experiments both of Langley and M. Carville (*Jour. de Thérap.*, January, 1875), section of the chorda tympani high up or low down after it has joined the lingual nerves did not affect the action of the drug. Further, in another of M. Carville's experiments, the lingual and pneumogastric nerves and the upper sympathetic cervical ganglia having all been cut or destroyed, jaborandi still produced free salivation.

Evidently the drug acts either upon the glandular tissue or upon the nerve-endings within the gland. As an injection of atropia immediately arrested the secretion in the experiment last mentioned, it appears probable that the drug influences the peripheries of the nerves. The sweat produced by jaborandi is often enormous in quantity (nine to fifteen ounces by estimation). It is stated to be at first acid, then neutral, and, finally, often clearly alkaline. In the analyses of M. Robin the chlorides were found in excess, the carbonates and phosphates in very minute amount, and the urea in more than five times its normal proportion, the amount eliminated in the sweating being estimated at from ten to fifteen grains. MM. Hardy and Ball believed that in their experiments the average amount of urea eliminated by the skin was seventeen grains (*Four. de Thérap.*, 1874). The urine appears not to be usually acted upon. Hardy and Ball state that urea is diminished, but neither their experiments nor those of others are yet sufficient to determine what is the general effect of the drug upon the elimination of urea. M. Gubler states that when jaborandi is given in small repeated doses it acts as a diuretic.

M. Robin affirms that before and during the early stages of the sweating from jaborandi the temperature rises 1° to 2° Fahr., but afterwards falls as much below the normal point, and remains depressed for one or two days. In Ringer's experiments (*The Lancet*, vol. i. p. 157, 1873) the primary rise of temperature occurred only once, and the fall, which was always present, was not persistent, the bodily heat recovering itself in a few hours.

In the experiments of F. Riegel (*Berliner Klinische Wochenschrift*, 1875, p. 86) the rise of temperature was either altogether absent or was very trifling, so that at the farthest the primary increase of the bodily heat can be looked upon only as an occasional and non-essential feature of the action of the drug.

The only study of the action of the drug upon the circulation as yet published is that of Mr. Langley. He found that in both the rabbit and the dog the injection of jaborandi into the jugular vein produced an immediate fall of the pulse. This fall was probably due to stimulation of the inhibitory nerves, since in the frog the drug produced cardiac arrest in diastole, which, when atropia was injected, immediately disappeared, the heart-action at once recommencing. Mr. Langley believed that he could see in the frog's web dilatation of the arteries follow the injection of the drug. In a rabbit in which the sympathetic had been destroyed upon one side, intravenous injection of the remedy was followed by contraction of the vessels on that side only. These experiments are not entitled to much weight; and as Dr. Langley found that the arterial pressure is not materially affected, being only slightly lowered, it seems most probable that the drug exerts no action on the vaso-motor nerves; but further investigations are necessary to determine this.

During the constitutional action of jaborandi, contraction of the pupil and some disturbance of vision have been noted by several observers. The local action

of the drug upon the organ has been especially investigated by Mr. John Tweedy (*The Lancet*, 1875, vol. i. p. 159). He found that when applied to the eye jaborandi contracts the pupil, produces impairment of vision by benumbing the retina, and also causes tension of the accommodative apparatus, with approximation of the nearest and farthest points of distinct vision.

In man, muscular tremblings have been observed several times during the action of jaborandi, and Mr. Langley found that in the frog it induces violent convulsions, without affecting perceptibly the irritability of the nerves or muscles. As the convulsions were not influenced by excision of the brain, but were arrested by destruction of the cord, they are probably spinal in origin.

It is asserted that jaborandi and atropia are antagonistic (*Berliner Klinische Wochenschrift*, May 3, 1875.)

CORRESPONDENCE.

NEW YORK, June 5, 1875.

SATURDAY afternoon is Prof. Thomas's time for operations at the Woman's Hospital. To give your readers some idea of his methods of treatment, I shall make the first part of my letter really a clinical report.

1. *Cauliflower excrescence on the cervix uteri*.—This was supposed to be of malignant character; but at all events Dr. Thomas deemed it good surgery to remove the entire cervix, and this was accomplished with remarkable facility by means of the galvano-cautery.

The battery he used was the zinc and carbon one of Dr. Byrne, of Brooklyn, in which the fluid (the bichromate of potassium and sulphuric acid solution) is kept in motion by a current of air forced into it from an india-rubber hand-bulb as often as necessary. A Sims speculum having been introduced, the uterus was dragged well down towards the ostium vaginæ, and the cervix secured by the teeth of a strong pair of grappling-forceps, whose square shoulders also prevented the platinum wire of the instrument from slipping off. After the wire was adjusted, it took just five minutes to cut through the uterine tissues, and there was not a drop of hemorrhage. In place of the cervix there was now a cup-shaped depression, with a clean-cut surface. Every portion of the growth had been completely removed. The mucous membrane of the vagina was slightly burned during the operation by reflected heat, but the injury was trifling, and the insertion of a roll of cotton saturated with glycerin, which would be useful as a soothing dressing, as well as to keep the vaginal surfaces separated, was the only after-treatment required.

Dr. Thomas said he would never think of operating in any other way in these cases, as furious hemorrhage, often endangering the life of the patient, generally results from other methods. He has performed the operation with the galvano-cautery over one hundred times, and never met with the slightest bad result, except in one case, when pelvic abscess followed. This

could not be attributed to the method, however, but might result from any form of operation.

2. *Menorrhagia*.—This was of long standing, and supposed to be due to granular excrescences on the lining mucous membrane of the uterus. As the patient was a single woman, a sponge-tent had been introduced the day before; but this is seldom necessary in those who have borne children. The tent removed, Dr. Thomas introduced his curette, which consists of a simple loop of copper wire, which can be readily bent in any direction, and soon confirmed the diagnosis by exhibiting some of the characteristic granulations, or fungoid growths, which are such a frequent cause of menorrhagia. He then scraped lightly, but carefully, the whole internal surface of the uterus, bringing away a considerable number of these; and the operation was completed. This procedure has been decried as dangerous and barbarous in the extreme (in fact, entirely beyond the bounds of legitimacy); but Dr. Thomas has found in it a remarkably simple means of completely curing an exceedingly numerous and distressing class of cases, and one which is entirely safe when used with proper precautions. He has employed it an innumerable number of times, and never met with the slightest accident, except in two cases. In one considerable hemorrhage, and in the other dangerous peritonitis, resulted. In the latter case, however, he used Sims's steel instrument,—which he considers dangerous, unless employed with great caution.

Not a month passes in which the curette is not applied at least once at his clinic at the College of Physicians and Surgeons, and, though the patients are obliged to return to their homes afterwards, the results are always most gratifying. Occasionally it is necessary to repeat the little operation. The condition of the uterine mucous membrane thus treated is very rare in unmarried females; resulting, as a rule, from abortion or normal parturition.

3. *Retroversion complicated by a fibroid in the posterior wall of the uterus*.—This fibroid feels precisely like one of the ovaries to the touch, but that it is not is proved by the fact that it is firmly attached to the uterus, moving whenever the latter is moved. Nearly all the different kinds of uterine displacements are amenable to treatment by some of the various forms of pessaries now in use; but three conditions may complicate a retroversion or retroflexion, any one of which may completely baffle all our efforts to retain the uterus in position. These are, first, the presence of a fibroid; second, old retro-uterine peritonitis; third, the absence of a cervix. In the present instance Dr. Thomas had the patient completely etherized, and then, inserting two fingers into the vagina, he pressed up the fundus till the organ was completely restored to position, as shown by the sound. Had he not succeeded in doing this completely by this manœuvre, he would have accomplished it by the use of the uterine repositior. He then introduced his own retroversion pessary, but expressed considerable doubt as to whether the patient would be able to tolerate it, on account of the presence of the fibroid.

In introducing pessaries, Dr. Thomas always keeps a Sims speculum in the vagina; as the instrument can be thus slipped up into place much more easily and accurately by the operator, and with much less pain and annoyance to the patient. Dr. Cutter, of Boston, was present on this occasion, and Prof. Thomas complimented him highly on the great efficiency of his improved pessaries. Dr. Cutter then spoke of the interesting investigations in the treatment of fibroids by electrolysis, which he and Dr. Kimball, of Lowell, have recently been making. They have now operated in forty or forty-five cases, often with the result of completely removing the tumor (even when of the size of a man's head), and, when this could not be done, of completely arresting its further growth. One death has occurred; but, as it took place some time after the operation, and no post-mortem could be obtained, it is questionable whether it should be attributed entirely to that. They use a battery, the surface of whose plates amounts to sixteen and a half square feet. The electrolysis is performed by corrugated needles piercing through the abdominal walls into the fibroid, and the effect produced is often so powerful as to occasion temporary syncope. We believe the idea was suggested to Dr. Cutter by General Kilpatrick's case, where a tumor was completely gotten rid of in this way by Dr. Lincoln, now of this city. Dr. Thomas was so impressed with the importance of these investigations that he promised Dr. Cutter to come on to Boston to witness the operation as soon as he could get three or four suitable cases together.

A great outcry having lately been raised in some of the public prints against the unwholesomeness of the material used for filling in the Harlem Flats (a section of the city known for a long time back as simply a pestilential swamp), a committee of the Police Surgeons visited the locality, at the request of the Board of Police Commissioners, for the purpose of investigating the matter; who reported that the filling was conducted in accordance with the principles of sanitary science, and that 95 per cent. of the material used consisted of ashes and street-sweepings; only 2 or 3 per cent. being composed of garbage or dead vegetable matter. From the directly contrary testimony of many clergymen and other intelligent residents of the neighborhood, as well as of several physicians of excellent standing, whose families are not only annoyed by the disgusting odors constantly arising from the filled-in district, but actually suffering from the disease engendered by it, and especially when we remember that this filling-in is done by parties who receive their contracts directly from the Police Department, and that each of these surgeons receives a considerable annual salary from the same department, one can hardly resist the unwelcome conclusion that this belongs without doubt to the order of "white-washing" reports.

One of the surgeons who signed the report having stated that it was not strictly in accordance with the truth, he was summoned before the Board of Police Commissioners to explain why he did so under the cir-

circumstances, when he said that the report was made out by Dr. Henry, President of the Board of Surgeons, and no opportunity was given the other members for discussing it, but that he signed it for the sake of preventing ill feeling on the part of his fellows.

That the Police Commissioners themselves are not altogether satisfied with the report is shown by the fact that they have requested a statement of the official opinion of the Board of Health in regard to the condition of the Harlem Flats. The matter was referred to the Sanitary Committee, who will make their report at an early date. At the last meeting of the Board of Police Commissioners it was resolved that the street-refuse should, unless approved by the Board of Health as suitable for filling in sunken lots, be taken to sea and discharged there, or otherwise disposed of outside of the city limits.

Smallpox has been increasing here somewhat of late, the number of cases for the last three weeks being 97, 111, and 117 respectively; and the Board of Health have appointed an additional corps of vaccinators in consequence, to serve for one month.

The demand for seats for the performance at the Academy of Music in aid of the Central Dispensary became so enormous that the managers announced that seats would be sold for the orchestra; but, this also proving an insufficient accommodation, they requested Mr. Rignold to give a *matinée* performance in addition. To this he readily consented; and there is no doubt that the Academy will be crowded to its utmost capacity, both afternoon and evening.

Dr. Mary Putnam Jacobi has recently received from Paris the bronze medal, awarded three years ago by the Academy of Medicine, for her graduating thesis. This gives her a rank of from fifth to eighth in a class of three hundred; gold medals being given to the first and bronze medals to the second four. This lady seems to have evinced an early taste for the study of medicine, for we learn from good authority that when about eight years of age she came in from the back yard one day and requested a knife. "What do you want it for?" asked her mother. "I have found a dead toad," she replied, "and I want to investigate his circulation."

PERTINAX.

135 SOUTH FIFTEENTH STREET, PHILADA., June 17, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR DOCTOR,—In your article on salicylic acid, in the last number of the *Times*, you have quite misrepresented a statement of mine at the Pennsylvania Hospital of having cured a case of favus by a saturated solution of the acid. It was by a saturated tincture, or, if you choose, by a saturated *alcoholic solution*. This, you can readily see, will be of importance to any one following my trial of it. The acid's want of solubility in water has long been practically known at the Hospital. I have myself since the 1st of February been using the aqueous solution only as a final wash on stumps and wounds prior to closing them. I have used the acid in collodion (5 grs. to $\bar{\text{z}}$), to destroy the burn-

ing and irritating effects which have heretofore rendered that article almost useless in surgery. I have used such collodion by strips of tarlatan gauze, and got most perfect coaptation of wounds and complete union when the part has been thoroughly enveloped with cotton wadding impregnated with the acid and applied according to Prof. Guérin's method,—*i.e.*, for a considerable distance around the injured part. In this way I have had direct union of compound fractures of the head, face, arms, and legs, and of stumps of the phalanges and fore-arm. In all such dressings torsion was the means of arresting hemorrhage employed.

The impregnation of the cotton was made from the saturated tincture by means of an atomizer. I have frequently seen most satisfactory results from the collodion charged with the acid in erysipelas and chronic eczema, applied as iodine used to be in the former of these complaints. My experience with it will suggest its having a fair trial in a thousand different ways.

Very truly,

ADDINELL HEWSON.

PROCEEDINGS OF SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

DECEMBER 2, 1874.

DR. ALBERT H. SMITH read a paper on "Quinia as a Stimulant to the Pregnant Uterus." The author stated that his views were founded upon an extensive and careful trial of the remedy upon the pregnant uterus. As to its effects upon the organ in a quiescent state, he had only been able to make observations incidentally, but thought his experience was sufficient to establish the fact that quinia has no power in itself to excite uterine contractions. He had at times had under care pregnant women, with diseases of malarial origin, in whom quinia sulphate in doses varying from twelve to twenty grains in the twenty-four hours had not disturbed the uterus; still further, in cases in which, with the symptoms of malarial poisoning, the pregnant uterus had already become disturbed, where there were pelvic distress, tenesmus, and sacro-lumbar pain of a paroxysmal character, quinia in large doses had not only relieved the constitutional symptoms, but also quieted the local pains.

As to the effect of quinia upon contractions of the uterus developed prematurely, from accidental causes, in abortions or early deliveries, Dr. Smith's observations have been limited; but in five cases he had administered fifteen grains of the sulphate, after the process had advanced beyond the possibility of arrest and the pains were recurring with regularity, and in none of these instances was there any perceptible increase in the frequency or efficiency of the contractions, or, when there was hemorrhage, any lessening of the flow.

When the uterus is in normal labor at full period of gestation, then quinia plays an active part in aiding parturition. For a number of years Dr. Smith has been in the habit of using quinia occasionally in cases of marked inertia during the stage of dilatation, in combination with other remedies, such as the administration of diffusible stimulants or hot drinks, abdominal friction, or any other means that might suggest itself in preference to the use of ergot, which he had long pro-

scribed on account of its dangerous influences upon the child, its occasional fearful risk to the mother, and its annoying uncertainty of action.

For a few months past, he had been experimenting with sulphate of quinia as a promoter of normal labor from the onset of the process, and had come to the following settled conclusions: quinia increases the activity of the normal uterine contractions; the pains becoming more frequent and more intense, the expulsive power being greater, while the yielding of the circular fibres of the os is more prompt; the contractions maintaining their proper intermittent character, the relaxation and rest in the interval being complete; showing in this respect an entirely different action from the continuous spasmodic contraction caused by ergot. The efficiency of the contraction may be judged of from the fact that in the thirty-two cases having no obstruction, although many were primiparæ, and a larger than usual proportion occipito-posterior positions, the average duration of active labor after the quinia was administered was about one hour. In a considerable number of the cases included Dr. Smith had in several previous labors required to use forceps to combat inertia in the second stage.

Quinia promotes permanent tonic contraction of the uterus, after the expulsion of the placenta. Several of the patients had had flooding under his care previously, some of them habitually, and some stated that they always had a profuse and weakening flow in all their other labors. In the whole forty-two cases Dr. Smith had not one case of flooding, and, as a rule, the uterus contracted firmly after the second stage was completed, and showed no tendency to relax afterwards.

It diminishes the lochial discharge to a normal standard; many of the patients expressed surprise at the small amount of flow during the twenty-four hours following labor. Its use is followed by less after-pains than usual in a majority of cases. It reduces the frequency of the mother's pulse, and relieves the nervous demoralization so often seen in the first stage of labor.

Given during parturition, it never disturbs the brain or causes its usual unpleasant effects, even in patients who at other times are very susceptible to its influence. Although the dose has been uniformly fifteen grains, in only one case was the slightest sensation of cinchonism manifest, and that lasting only a moment, in a lady who knew what she had taken, and was, perhaps, quite prepared to feel it.

Although fully persuaded of the value of quinia in parturition, Dr. Smith believes that it has no inherent property of stimulating the gravid uterus to contraction; being inert as to any effect upon the womb in a quiescent state, and having no decided action in accidental labors at any period of gestation. That to its property as a general stimulant and promoter of vital energy and functional activity, and to that alone, is due its influence upon the uterus in normal parturition; producing then no action peculiar to itself, but merely increasing the power of the uterus to expel its contents by its own natural method, converting what is a defective or even pathological action into a simple physiological process. That by availing ourselves of this power we may by administering full doses of the sulphate of quinia at the onset of labor favor the rapid and safe termination of what might otherwise be a tedious and exhausting work.

ZIEMSEN'S CYCLOPÆDIA OF MEDICINE.—On page 290 of vol. iii., second text line from the bottom, the word "ounces" should read "drachms." As the error might lead to serious consequences, we would thank our exchanges to give publicity to this notice.—*N. Y. Medical Record.*

REVIEWS AND BOOK NOTICES.

A MEDICAL VOCABULARY. By R. G. MAYNE, M.D., LL.D., and J. MAYNE, M.D., F.R.C.S. Edin., L.S.A. Fourth Edition, Revised and Enlarged. Philadelphia, Lindsay & Blakiston, 1875.

This little work is one of the most convenient and reliable medical vocabularies which has been given to the profession.

The definitions sometimes lack clearness, from their exceeding brevity and terseness; but this is largely compensated for by the fulness and accuracy with which the derivation of each word is given, and by the unusual number of words belonging to the collateral sciences which this condensation has enabled the editors to introduce.

SELECTIONS.

A REMARKABLE CASE OF CATALEPSY AT THE COCHIN HOSPITAL, PARIS.—The case of catalepsy which has been under observation at this hospital, and which has been attended with sufficient publicity to allow the most satisfactory verification, cannot fail to afford interesting matter for thought to the physician as well as to the philosopher and historian. There is here no question of those facts which mysticism, fanaticism, or credulity have often shrouded in mystery by attributing to them a miraculous or supernatural aspect, turned to profit according to the requirements of the moment: here there is only question of a pathological fact of an exclusively scientific nature. A patient, Marie Lecomte, who had come into Dr. Desprès's wards for a surgical affection, was soon afterwards attacked with dysmenorrhœa and uncontrollable vomitings; these complications were followed by nervous aphonia and suppression of the urinary excretion, then supplementary derivation of urine by vomitings. At the beginning of April the urinary function, which had long been suspended, was re-established, when on April 5 the patient fell into a lethargy; her breathing was imperceptible, her lips were pink, and her complexion rather roseate than pale. The trunk and limbs were in a complete state of relaxation; the pulse was normal; involuntary motion was quite abolished; the finger, placed through the half-opened mouth on the glottis, the most sensitive point in the whole animal economy, provoked neither cough nor any other movement. M. Desprès, therefore, ordered that no food whatever should be given to the patient, even with the canula used to feed paralytic patients, for fear that any attempts at giving nourishment should produce asphyxia. On April 6 the whole of the patient's muscles were tense and hard; they were contracted. It was cadaveric rigidity, minus death, for the pulse registered seventy pulsations, and the temperature of the body, taken with a thermometer placed under the armpits, measured 100.4° Fahr. At this time the patient was cataleptic, and the lethargy continued. This condition lasted six days, during which the patient remained apparently dead and took no nourishment. During this attack the facts observed were, in the first place, muscular rigidity. The limbs were in a state of extension; the arms fixed tightly to the body gave the patient a resemblance to a mummy; it was necessary to use force to change the position of a limb. The limbs, hands, and fingers remained for many hours in the very fantastic positions in which they were placed, and then gradually returned by jerks to the position whence they had been removed, and so remained in the same previous state of contraction. There was not the slightest relaxation of the muscular

contraction. The patient was seen every hour of the day and night, and her condition was always the same. Many attempts were made to awaken the patient, such as pricking the most sensitive points, introducing rigid stems into the nostrils; but nothing had any effect, and the physicians who used these means were convinced that the abolition of the reflex movements was a certain fact.

M. Desprès again tried an experiment, tending to show that the muscular contraction was involuntary, as a conclusive proof. The muscles of the abdomen contracted like those of the rest of the body, and retained the form imparted to them. By forcibly applying the hand to the abdomen, the muscles were depressed, and the imprint of the hand remained visible during three minutes at least. These muscles remained contracted in the position imparted to them, a thing which could never be obtained by the effort of the will under any circumstances. On the seventh day of the crisis, the patient murmured some words, and asked for something to drink; she drank a small quantity of coffee and broth, which she partly vomited some hours after. On the eighth day the patient fell back again into the cataleptic condition, the fresh crisis lasting forty hours. On the twelfth day there was a fresh partial awakening. The patient called her neighbors, the house-surgeon, and the sister of the ward, without recognizing the persons she called and without answering the questions addressed to her; she drank some more broth and coffee, which she vomited the next day. She had a relapse on the thirteenth day, with catalepsy and lethargy, lasting sixteen hours. On the fourteenth day there was partial awakening; then catalepsy, lasting about eight hours in the night. In the intervals of the crisis the patient drank broth and coffee; but, as she afterwards vomited a portion of what she had taken, the abstinence had markedly emaciated her, and the small pulse, marking 100, showed that want of food was producing its usual effects. From that time the cataleptic crisis ceased. The patient remained in a state of dreamy wakefulness,—that is to say, of somnambulism. She did not recognize any one, but was yet able to take drink, and specially coffee and milk. On the seventeenth day a fresh symptom made its appearance. The patient during her dream had complained of not being able to see, and believed herself to be blind. As a matter of fact, a shining object placed before her eyes, and even the light of day, did not seem to be perceived by her. By automatic movements, against which all efforts were useless, she got her fingers to her eyes, and rubbed them with a sort of febrile excitement to such an extent that it was found necessary to tie her hands. Finally, her sight returned to her on the eighteenth day; she recognized some people in the ward, and was able to take liquid food in a regular way. On the twenty-fifth day the patient did not vomit any more, but retained the nourishment she took; she was entirely convalescent, and only complained of pains in her limbs, which she compared to those caused by fatigue. On the thirtieth day she was able to get up, and on May 5 she was entirely cured.

Cases like that which has occurred at the Cochin Hospital are not new, but they have rarely been well observed. The remarkable researches of Professor Lasègue have made known the intermittent catalepsy of hysterical subjects, of ecstatic maniacs, and even of healthy persons. It is a condition which may be provoked at will or which overtakes patients somewhat suddenly; as in the case of the judge quoted by Fehr,* who, having been insulted on the bench, and having risen to reply, remained with outstretched arm and open mouth in a state of catalepsy which lasted more than a quarter of an hour.

The catalepsy complicated with somnambulism of hysterical patients, which appears in crises of an hour or longer, is now thoroughly well known: if it be not simulated, it is at least kept up by the will of the patients, or by a tendency which they could resist if they would. This kind of catalepsy is almost exclusively the melancholy privilege of women and priests.† Cataleptics who have taken advantage of religious superstition, and who have sometimes been encouraged by the Roman Catholic Church, belong to that group of cases in which catalepsy is complicated with somnambulism or ecstasy. Louise Lateau, an account of whom will be found at pp. 128 and 158 of the *Medical Record*, is a cataleptic of this kind. The cataleptic of the Cochin Hospital presents another variety of catalepsy: the attack begins with lethargic coma, and generalized muscular contraction comes on twenty-four hours afterwards. When the patient awakes she is somnambulant. The catalepsy, accompanied by lethargy, lasts six full days, during which there is apparent death. After the awakening there are three relapses, and the disorder only seems to yield bit by bit, after alternations of awakening and lethargy for several days. Here is a case of disorder which is nowadays called neurosis, and connected with the hysterical temperament, in which nothing of the marvellous has been observed. Marie Lecomte is a foundling, four-and-twenty years old, who had never left the Foundling Hospital and the farm where she had been boarded out. A quiet and well-conducted unmarried woman, she had neither exaggerated religious ideas nor vicious habits. Both before and after her attack, during the state of ecstasy and somnambulism which followed the six days of catalepsy, she held no continuous conversation, said no prayer, nor pronounced the name of God; but asked for ice or water to drink, called those of her hospital neighbors whom she knew best; in fact, spoke naturally according to her tastes and habits. As the Paris hospitals, open to every one, are usually given in charge to medical men who are accustomed to sick people and see things from a positive point of view, in accordance with science, no attempt was made to find any supernatural utterances in the words spoken by the patient. The case of Marie Lecomte, which should be published with all its details, becomes a scientific fact, with regard to its authenticity far above the facts reported in the sixteenth, seventeenth, and even eighteenth centuries. At those epochs, in fact, the hysterical cataleptics or insane devotees passed for the elect of God, and the ecstatic or somnambulant cataleptics who did not speak of the Divinity were exorcised and even burned. As regards lethargy and abstinence from food, Marie Lecomte is not the most remarkable type. Some maniacs have remained equally long in the cataleptic and lethargic state; but the relation of the facts is not clear, and it is not recorded if the muscular system was contracted during the whole time the fit seemed to last, as it was with Marie Lecomte during six whole days.

It may not be unadvisable here to reply to a question which may arise in some minds. It is whether, in presence of this state of apparent death, it may not have been possible that ignorant persons may have believed death to be real, and have interred the patient. The answer is easy: the most inexperienced practitioner who might have felt the pulse could not have had one moment's doubt on the subject, and there is ground for believing that if, since the beginning of this century, a cataleptic patient, in a state of lethargy, has been interred alive, the medical man could never have looked at the supposed corpse. This is clearly reassuring, and it may be deduced from the case of

* Fehr, *Hiera Picra*, seu de Absinthia, 1667.

† Rondelet speaks of a priest who fell into ecstatic catalepsy when the history of the Passion was read. (*Methodus Cur. Morb.*, ed. 1583, lib. i. cap. 20.)

Marie Lecomte that, notwithstanding the appearances of death, the signs of life were so decided that the most ignorant of practitioners could not have felt for an instant the slightest doubt as to the vitality of the patient.—*London Medical Record.*

MACEWEN ON PENETRATING WOUNDS OF THORAX AND ABDOMEN TREATED ANTISEPTICALLY.—Dr. William MacEwen (*Glasgow Medical Journal*, January, 1875) gives four cases, all treated in the same way, and all with equally good results.

Case I.—A boy, aged twelve, was stabbed in the back, and only after much and careful probing was a visceral wound found, and then in the lung-substance a piece of the blade of a pocket-knife; this was after some difficulty extracted, and was the means of detecting the assailant by fitting his broken knife. The wound in this, as in other cases, was thoroughly injected with carbolic lotion (one part in forty) and then dressed in the usual way with antiseptic gauze. The probing was in the first instance persevered with, in consequence of a peculiar catching at the throat during breathing. In three weeks the patient was perfectly well.

Case II.—A man, aged forty-six, was stabbed on the left side of the chest, the wound passing into the anterior mediastinum. The heart could be felt by the finger passed into the wound. The treatment was the same, sutures being passed and tightened as soon as bleeding ceased. He was enabled to return to work, well, in less than three weeks.

In remarking on these two cases, Dr. MacEwen points out that the antiseptic treatment enables a careful examination of the wound to be made with the probe or finger in safety, while in the first case a probable source of fatality was removed. This he claims as an advance in the surgery of these cases instead of the ordinary plan of not touching them, and thus "groping in the dark" in the after-treatment.

Case III.—A lad, aged seventeen, was stabbed in the abdomen, a knuckle of uninjured intestine being held between the lips of the wound. The wound was injected, sutures passed and tightened after the bleeding ceased, and lead and opium given internally. In ten days he was well enough to desire to get up, and the wound had healed; but he was kept quiet for three weeks.

Case IV.—A man, aged twenty-eight, with an abdominal wound of three inches, and another of one inch, the former evidently perforating the intestine. The same surgical treatment was adopted, along with morphia suppositories, the bowels being kept quiet for a fortnight. In a month he was well and strong.

[We have seen similar cases treated antiseptically in Edinburgh with equally good results, and think that Dr. MacEwen is right in advocating careful examination with antiseptic precautions, in preference to the usual treatment recommended in the surgical textbooks.—*Rep.*] *London Medical Record.*

GRAS ON MICROSCOPIC EXAMINATION OF BLUE LINES ON THE GUMS SUPPOSED TO BE DUE TO LEAD-POISONING.—*La Revue Médicale* for April 12, 1875, quotes a paper by Dr. Gras on this subject from the *Archives de Médecine Navale*. He insists strongly that the lead-line is no mere deposit of that metal in or on the epithelial cells or connective tissue of the gum. It is due to a transformation of a soluble salt of lead into a sulphide of that metal during the slow circulation of the blood in the very minute capillaries of the gum. He says the demonstration is exceedingly simple, and almost painless. When we are in doubt whether a given blue-line on the gum be due to lead or not, we should excise a fragment of the gum containing the line with a fine sharp scalpel or the point of a lancet, wash it with a camel's-hair pencil, and add a drop of glycerin;

if necessary, flatten it out with needles, and examine it under the microscope with a low power. If the line be due to lead, in the midst of the normal tissues of the gum we shall find capillaries injected, filled and obstructed by blackish granules. These capillaries are in loops, or semicircular, or like double hooks, the outlines varying somewhat according to the section. In very old lead-lines the capillary walls are less evident, and their outlines somewhat indistinct. If a piece of buccal mucous membrane be excised, we should use carmine with glycerin, and a little dilute acetic acid, which shows the mucous papillæ, and the capillary net-work. He suggests that in fatal lead-colic the intestinal capillaries and the nerves of the solar plexus should be examined in the same way for lead. [The Reporter does not know to whom the credit of the suggestion belongs, but it has long since been proposed to examine the lead-line by a simple microscope, or, in other words, a one- or two-inch biconvex lens; when, if in the capillaries, as the true lead-line is, it will be seen clearly to be dotted, and to follow the course of the vessels. It will thus be seldom necessary to remove any of the gum in the living subject; though after death this suggestion of M. Gras may doubtless be of considerable use].—W. BATHURST WOODMAN, M.D., in *Lond. Medical Record.*

TREATMENT OF DISEASE OF THE HEART.—Dr. J. Milner Fothergill, in concluding an article in the *London Lancet* of May 29, says,—

Of preventive measures nothing can be said at present; but of measures palliative or curative the following brief summary may be made:

1. That it is of the utmost importance in the treatment of primary disease of the heart to reduce to a minimum the calls upon that organ. Consequently, light labor alone must be attempted; and rest in bed is often very desirable at the commencement of a course of treatment, as well as at intervals afterwards.

2. Frequently much relief can be afforded when dropsy is present by unloading the distended venous system. Brisk catharsis gives great relief, and does not depress the patient, as might be apprehended.

3. In all cases the heart must be acted upon directly by agents which increase the vigor of the ventricular contractions, of which digitalis is the chief. This agent may be given uninterruptedly for years without any so-called cumulative action, if the cases are properly selected. If given in improper cases, unpleasant consequences may follow its administration.

4. It is also very desirable that the nutrition of the heart be maintained by good food and iron in addition to the means mentioned above. Improvement in the general condition facilitates the action of the special remedies.

By combination of these measures, adapted to the needs of each individual case, much may be done in cases of primary disease of the heart. What are the indications for treatment and the measures to be resorted to in cases of secondary affections of the heart—that is, where the heart-failure is due to some primary ailment standing in a casual relationship to it—will engage our attention on some future occasion.

PLANAT ON Picrotoxine AS A REMEDY FOR EPILEPSY (*London Medical Record*, May 26, 1875).—To M. Felix Planat's work on this subject has been awarded one of the premiums under the foundation of the Prix Barbier at the disposal of the Paris Academy of Medicine. M. Planat's researches, as recorded in his *Recherches physiologiques et thérapeutiques sur la Picrotoxine*, have been directed to the endeavor to find some remedy for epilepsy. To this end he proposes, not as a specific, but as a really useful medicine, picrotoxine, the active principle of *cocculus indicus*. He administers it in the following way: *cocculus indicus*, 200

grammes; alcohol, 1000 grammes; allowed to macerate for three weeks. Give two to three drops of the alcoholic tincture, increasing from two drops daily, then diminishing. The treatment should be prolonged for several months, or even a year. According to M. Planat, the anatomical seat of epilepsy is in the spinal marrow; the contraction of the sanguineous capillaries brings on a bulbar ischæmia, and this ischæmia in its turn produces convulsions. The picrotoxine acts on the bulb; it is a convulsant poison: therefore, in accordance with the axiom "similia similibus," it will cure epileptic convulsions.

The commission appointed to adjudge the Barbier prize, however, guarantees neither M. Planat's theory nor his experiments, although he asserts that he has by the administration of picrotoxine brought on convulsions, with foam at the mouth, in a rabbit, a kitten, and in animals of a lower organization, as frogs, crabs, and even snails and slugs. Neither does the commission guarantee the veracity of the numerous cures with which M. Planat credits himself. The Academy, however, has shown its estimation of meritorious work carried on through twelve years, by the award of a premium of five hundred francs to M. Planat.

GLEANINGS FROM OUR EXCHANGES.

THE PATHOLOGY OF PROGRESSIVE MUSCULAR ATROPHY.—Dr. Troisier recently brought the following case to the attention of the Société Anatomique of Paris: In a male, 27 years of age, loss of motor power with atrophy of the muscles of the upper limbs began fifteen months before death, the muscles of the right shoulder being first affected; the fatal termination was due to involvement of the intercostals and diaphragm. Examination showed simple atrophy, without loss of striation, of many of the fibres of the various muscles, with an increased amount of interstitial tissue and fat. Both roots of the spinal accessory and the root of the hypoglossal nerve were atrophied, gray, and translucent; the microscope showing simple atrophy of their fibres with preservation of myeline. Similar changes were noticed in the eight upper anterior spinal roots, most marked on the right side, the posterior roots being intact. Examination of the spinal cord showed almost entire absence of the characteristic large branched nerve-cells in the anterior cornua; scanty granular masses represented those which had disappeared. These changes were limited almost entirely to the cervical region of the cord.

Dr. Troisier thought that the disease had arisen in a sub-inflammatory condition of the gray matter itself, the atrophy of the cells in the anterior cornua being the primary lesion and the changes in the nerves secondary. The change in the muscles was one of simple atrophy, accompanied by the multiplication of nuclei of the sarcolemma. Dr. Charcot remarked on the value of the case as showing the connection between lesions of the anterior cornua and progressive muscular atrophy. —*Lancet*, May 29.

TREATMENT OF ACUTE NASAL CATARRH, ETC., BY THE TINCTURE OF THE CHLORIDE OF IRON.—J. S. Prout, M.D. (*New York Medical Record*, June 12), recommends the use of tinctura ferri chloridi in large doses in the treatment of coryza. There is often an abortive action on the inflammation. In half an hour relief may be felt, which may remain permanent, or a cure may require a few repetitions of the dose.

Dr. Bull writes to Dr. P. as follows: "I have used the tincture of the sesquichloride of iron quite frequently in cases of recent or incipient nasal catarrh, what is ordi-

narily called 'a cold in the head,' and almost invariably with a rapid beneficial effect. I give it as soon as the patient complains of the sense of fullness in the nose and head, in doses of from ℥xx to 3ss, and repeat every hour. Usually, I have not been obliged to give more than four or five doses, and sometimes not more than two. I have taken it myself, and always with good results. But it must be given early; otherwise it fails in producing the desired effect. I have not noticed any bad effects from its use in such frequently repeated doses."

Dr. N. B. Sizer has also written to Dr. Prout, giving his experience with the remedy. He has noted twenty-eight cases in which the iron was used, and twenty-five of these were cured in from twenty-four to forty-eight hours.

"In those not cured," Dr. S. says, "the catarrhal inflammation was modified somewhat, but the disease ran its usual course. There was no personal idiosyncrasy, so far as known, to interfere with the curative results in these cases. The dose varied from three to thirty-five minims, with an equal amount of syrup or glycerin. The thirty-minim dose has been given to an infant, with wonderfully quick effect; done tentatively, however, and not as a usual thing."

The tendency of the iron to constipate may be very much lessened or entirely prevented by the addition of three or four drops of the tincture of belladonna to each dose.

EXCISION OF THE HIP-JOINT AND REMOVAL OF THE WHOLE OF THE ACETABULUM WITH A PORTION OF THE DORSUM ILII (*Lancet*, May 29).—A boy of 11, with a family history of phthisis, received a kick on the hip while at play. Lameness followed this, which was treated for some time by rest and extension. After some months he was improved, and treatment was discontinued. His health became worse, suppuration was established, and the hip became riddled with sinuses. He was admitted to the Southport Infirmary, under the care of Mr. George A. Woods, a year and ten months after the accident, in an extremely emaciated and exhausted condition, suffering from hectic. There were various sinuses above the great trochanter, and one large crescentic one extending from a little below the great trochanter four inches to the dorsum ilii. Dead bone could easily be detected with a probe. Chloroform having been given, a T-shaped incision was made for about six inches over the centre of the great trochanter, the limb was forcibly adducted and rotated inwards, and the head of the bone exposed to view, lying dislocated on the dorsum ilii. The head of the bone and the parts below for an inch and a half were then removed with the saw, and the acetabulum and adjoining parts being found diseased, these as well as a portion of the dorsum ilii and ischium were removed by the gouge. The case progressed satisfactorily for a considerable time, but the patient died six months later of kidney-disease. On examining the joint after death, the wound was found entirely healed, and there was good motion. Shortening, four and a half inches.

NEUTRALIZATION OF HYDRATE OF CHLORAL BY CARBONATE OF SODIUM.—M. Oré states that the addition of two drops of a ten per cent. solution of carbonate of sodium to fifteen grains of chloral dissolved in a drachm of water will not only neutralize the acidity of the chloral but will render the solution alkaline. This alkaline solution hinders the coagulation of the blood instead of occasioning it, and can therefore be injected into the veins without any risk of producing embolism. M. Oré strongly recommends this method of employing chloral as a means of producing anæsthesia in surgical operations.—*Practitioner*; from *Bull. Gén. de Thérap.*, February, 1875.

MISCELLANY.

A SIMPLE METHOD OF PREVENTING MASTURBATION IN CHILDREN.—Dr. PORRO (*Riv. di Medicina, Chir. et Terapeutica*, de Soresina) writes that he was consulted about a child, aged four and a half years, who was furiously addicted to onanism. It occurred to him that if the prepuce were closed by transfixing it by a gold ring,*—such as are worn in the ears by girls,—the performance of the act would be hindered. This method proved efficacious, and the health of the child, which had been enfeebled, was soon re-established. The presence of the ring did not render erection painful. The author adds that this means may be applicable to girls by thus transfixing the labia majora, joining them throughout their superior and middle thirds.—*Le Progrès Médical*, April 10, 1875; *St. Louis Clinical Record*.

BLOODING A KING.—The following extract from "The Greville Memoirs" gives a vivid idea of medical practice in 1820:

"February 4.—The new king (George IV.) has been desperately ill. He had a bad cold at Brighton, for which he lost eight ounces of blood; yet he afterwards had a severe oppression, amounting almost to suffocation, on his chest. Halford was gone to Windsor, and left orders with Knighton not to bleed him till his return. Knighton was afraid to bleed him. Bloomfield sent for Tierney, who took upon himself to extract fifty ounces from him. This gave him relief; he continued, however, dangerously ill, and on Wednesday he lost twenty ounces more. Yesterday afternoon he was materially better for the first time. Tierney certainly saved his life; for he must have died if he had not been bled."

A HINT FOR SMOKERS.—Reference is made in the last number of *Nature* to a property which cascarilla bark has in modifying the physiological effects of tobacco-smoking. The addition of a few very small fragments of the bark will, it is alleged, in most cases counteract the nauseating effects of strong tobacco, although if such a mixture of tobacco and cascarilla bark be smoked to excess, it will sometimes produce loss of appetite, and thirst, with vascular and nervous depression.

FOR COLD IN THE HEAD.—Hamilton recommends to mix carbolic acid, 10 drops, tincture of iodine and chloroform, each 7½ drops. A few drops are poured into a test-tube and heated over a spirit-lamp; when it begins to evaporate it is placed under the nostrils. Two minutes afterwards, the operation is repeated. Sneezing at first results, but relief soon follows.—*Journal of Applied Chemistry; Physician and Pharm.*

A MEDICAL man, who is posted in all the sciences, and who has lately cured a very bad case of "fits," considers it an illustration of the Darwinian doctrine of "survival of the fit-ist."—*Danbury News*.

THE *Irish Hospital Gazette* is dead. Immediate cause, absorption into the *Dublin Journal of Medical Sciences*; predisposing cause, probably, lack of subscribers. *Requiescat in pace*.

ONE thousand nine hundred and seventy-four patients were treated in the Pennsylvania Hospital, exclusive of the insane department, during the last year.

MESSRS. BRYANT AND DURHAM have been appointed lecturers on surgery at Guy's Hospital, in place of Messrs. John Birkett and Cooper Foster, resigned.

DR. TILT, of London, has been made a "Knight of the Crown of Italy" by the Italian Government.

THE cinchona-cultivation in Jamaica is said at last to be thoroughly assured of success.

FEVER without ague is no great shakes, so says a malarial exchange.

NOTES AND QUERIES.

MOUNT SAVAGE, ALLEGANY COUNTY, MD., June 16, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I beg leave to ask an answer and explanation of the following question: "Is the temperature of an inflamed part *greater* than the ordinary temperature of the body?" I have asked several physicians this question, and have received answers both in the affirmative and negative; so, as a last resort, I ask for an explanation through the columns of your journal. For my own part, I should say that it was greater, and give my reasons for so thinking from the following facts:

1. The arterial blood supplied to an inflamed limb is found less warm than the focus of inflammation.
2. That the venous blood, returning from an inflamed limb, though found less warm than the focus of inflammation, is found warmer than the arterial blood supplied to the limb.
3. That the venous blood returning from an inflamed limb is found warmer than the corresponding current on the opposite side of the body.

Now, I would ask, Does the temperature of the inflamed part exceed that of the left ventricle of the heart, or the temperature under the axilla? If not, is it on account of the increased flow of blood which an inflamed part receives, and which neutralizes, to a certain degree, the increased heat which arises?

I beg you will pardon my troubling you; but, so far, I do not feel satisfied with the explanations I have lately received.

Yours, etc.,

MEDICAL STUDENT.

OBITUARY NOTICE.

DR. J. P. ANDREWS, a prominent physician of Colerain, Lancaster County, Pennsylvania, was found, on the 7th inst., lying in his buggy unconscious, with blood flowing from his mouth and nostrils, and died in a very short time after being taken out.

Dr. Andrews was an accomplished physician, quite a noted local historian, and is also said to have been one of the best botanists in the State. At the time of his death, he was in his 56th year.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 15, 1875, TO JUNE 21, 1875, INCLUSIVE.

HASSON, A. B., SURGEON.—Granted leave of absence for twenty days. S. O. 121, Military Division of the Atlantic, June 15, 1875.

KOERPER, E. A., ASSISTANT-SURGEON.—Relieved from duty as Attending Surgeon, Detroit, and assigned to temporary duty at Fort Wayne, Michigan. S. O. 124, Military Division of the Atlantic, June 19, 1875.

SKINNER, JOHN O., ASSISTANT-SURGEON.—Assigned to duty at St. Augustine, Florida. S. O. 79, Department of the South, June 14, 1875.

* This is simply a revival of the operation of infibulation, practised by the ancient Romans upon gladiators during their training for the arena.

SATURDAY, JULY 3, 1875.

ORIGINAL COMMUNICATIONS.

LIVING ISSUE.

BY THEODORE H. SEYFERT, M.D.

LAW, like every other science, is progressive, and adapts itself readily to those changes which intellectual development points out for its equitable administration. The common law, for instance, is said to be the accumulated wisdom of a thousand years. It grows by time, and is strengthened by the added wisdom of succeeding generations. But were reason to remain silent before authority, good or bad, we would soon be in as ridiculous a position as if the laws of the Medes and Persians were our unalterable code.

Legal reports are full of what are called "overruled cases," which simply means that judicial interpretation is not infallible, and that a case decided one way may, upon subsequent examination and reflection, be differently decided. There is such a thing as *bad* law, as there is such a thing as an illogical conclusion; and a decision that is not based upon correct reasoning, although it may have the grandeur of "authority" about it, is faulty, and liable to be "overruled;" but in all cases where the "authorities" are supported by reason, they stand, as they deserve to.

The Dover case (referred to at length by Prof. Reese, in his article on "What Constitutes a Live Birth?" in the *Medical Times* of the 20th ult.) is one of a character rare in our jurisprudence, and might very properly have been treated as the first of its kind, deserving an exhaustive examination of the reason and the spirit of the law bearing upon the subject, independent of the decisions in previous cases of a similar character. In determining the question of what is *living issue* within the meaning of the law relative to the "tenancy by courtesy," we must have a *reasonable* interpretation of the words "born alive," and to assist in so interpreting these words is the object of this paper.

Among the canons of construction laid down by Blackstone is this: "Words are generally to be understood in their usual and most known signification; not so much regarding the propriety of grammar as their general and popular use." The word *born* is understood by all, and as it is so understood the law understands it. It is the act of coming into this life, into communication with the outer world; and until this is accomplished the being is not born. The condition in which it comes is next to be considered; it must be *born alive*. Is it not reasonable to suppose that what the law contemplates in this term is not a partial or a qualified life, but an absolute life? that is to say, that the issue when born must be possessed of *all* conditions necessary to existence? Keeping in view the common-sense canon of construction, let us refer to Prof. Reese's paper, in which I find it stated that in establishing the claim of a *tenant by courtesy*, "what the

law requires is simply *proof of life*,"—not evidence to prove that the issue possessed an independent existence, but simply that it lived after its complete extrusion from the mother. Neither does the doctor consider the amount of life as worthy of special attention, for he declares that "all we contend for is *life*, not the amount or quantity of life, but the fact of life."

The word in its general sense refers to "that state of animals and plants, or of an organized being, in which its natural functions and motions are performed, or in which its organs are capable of performing their functions" (Webster). This is the popular acceptance of the word, and in this sense we must regard it. The word is also used with reference to specific stages of existence: thus, we say cell-life or germ-life, embryonic life, foetal life, in order to distinguish them from one another as well as from that kind of life now under consideration, which we will term independent life. The principle of life mysteriously contained in the germ is the same life continued on in man; and if the presence of the vital principle is *all* that is contended for, then the vivified ovule itself, or the living embryo suddenly thrust forth from the mother at any period of its career, may justly be regarded as *living issue*. But something more than "proof of life" is demanded. The amount or quantity of life is a matter of importance, as the following quotation will show. Every legitimate infant *in ventre sa mere* is considered born for all beneficial purposes (that is, for those relating to its own interests), but "as it respects the rights of *others claiming through the child*, if it be born dead, or in such an early stage of pregnancy as to be *incapable* of living, it is to be considered as if it had never been born or conceived." (Blackstone, Book I. *130, note.) Here the amount is measured in pointedly excluding the child which, *though it is not dead*, is incapable of living.

"To discuss metaphysical subtleties on the subject of life before a court and jury" might, under certain circumstances, "befog and confuse plain common-sense jurymen;" but I trust that they could readily be made to comprehend the difference between the amount of life comprised in one individual and in the 800,000 composing the population of our city; or that the existence of a State depends upon the number and the varied duties of its people. In other words, they could be made to appreciate the difference between the life of one cell and that of the countless number composing the body,—between the life of a tissue or organ and that of the being of which it is only a part. We cannot declare a person is alive because the microscope reveals the fact that cell-life is not yet extinct; and I am confident that even an expert witness would hesitate long before admitting the existence of an individual when it depended upon such microscopic evidence.

Under ordinary circumstances, the longer a person is completely submerged the less life do we find in the body, and the chances of resuscitation are correspondingly diminished. Our restorative meas-

ures consist in stimulating cell-action by artificial respiration, warmth, etc., and if their use is not attended with success, then we assert that the individual is dead; not because life has entirely departed from the body, but because vitality has diminished to such an extent that we cannot recall into activity those functions upon which the life of the individual is dependent. Thus, a newly-born babe may be said to be dead if it is incapable of exercising those functions without which life cannot continue. Recognizing this fact, the counsel for the plaintiff in the Delaware trial (Stout vs. Killen) alleged that the life in the child was merely a prolongation of foetal existence; but the defence held that this doctrine was untenable, and by a dexterous use of the word "life" succeeded in befogging the jury to such an extent that they sustained the claim of the defendant, notwithstanding the learned judge's efforts to lead them to a right conclusion.

A child born without the ability to breathe is not alive in the meaning of the law. Air is indispensable to life; and, says Dr. Draper, "In this particular the Scriptures have summed up the deductions of modern physiology in a single line,—no metaphorical expression, but the simple assertion of a truth: He 'breathed into his nostrils the breath of life, and man became a living soul.'" It was originally held that crying was a necessary proof of a live birth, thus showing that, in the early life of this law, respiration was needed to indicate life. But afterwards it was said by a learned lawyer, Sir Edward Coke, that it *need not* cry, "for perchance it might be born dumb." This, however, does not exclude the conclusion that it must respire, and nowhere is it hinted that respiration is unnecessary. The excuse for not making crying an obligatory proof relates not to the lungs but to other organs,—those of the voice,—and there is no reason to believe that the law now does not require the child to breathe before it can be called "living issue." Unless a placenta is developed, the embryo lives and dies as an embryo, for its further progress is arrested, and it cannot pass into that stage of existence known as foetal. And so with the foetus: it must live and die as a foetus, and can never pass into an independent life without the use of its lungs.*

In this connection, "profound and learned theories upon the difference between intra- and extra-uterine life" might very properly be studied by the "ingenious counsel" and explained to the jury, who will be called upon to decide whether or not the child had a separate and independent life; whether or not it was alive as a being of this world.

Foetal life is a dependent life. The elaboration of the blood which is essential for its maintenance is performed through the instrumentality of the placenta,—the lungs of the foetus,—and this involves a different arrangement in the route of the circulation from that which exists when independent life is established and the individual elaborates its

own blood. From the placenta arterial blood passes to every part of the foetal system, distributing its oxygen and nutritive elements to every tissue. As venous or impure blood it is returned to the placental surface, where, by endosmotic action, it is relieved of its carbonic acid and again supplied with oxygen and nutriment from the blood of the mother. It is unnecessary to refer to the anatomical peculiarities of the foetal circulatory apparatus further than to say their existence is owing to the important fact that the foetus must receive its breath and nourishment through the placenta. During this period the lungs are two solid, almost impervious, and utterly useless organs, receiving no blood except that required for their nutrition. Yet they are compactly stowed away and carefully nourished until the time arrives when the child's existence will depend upon their coming promptly to its rescue.

When the child is born and separated from its mother, the whole current of the circulation must be changed, otherwise it cannot live. The blood can no longer go to the placenta, for the source whence it received its breath is cut off, therefore it speedily seeks another channel, and passes in large quantities to the lungs. Now it is that these organs are called upon to fulfil the purpose for which they were created,—that of substituting a function of the placenta, and establishing in the being an independent life.

An independent life, then, can be said to exist only after the child has come into actual relationship with the world through the respiratory function. Unless air enters the lungs, its condition is precisely the same as it would be in utero with its cord tightly ligated. The child does not necessarily die upon the instant, for during labor it may live for five minutes after the cord has ceased pulsating (Barnes). It would be interesting to know how long life can continue cut off from placental and aerial respiration. Dr. Barnes states that a living child has been removed from the dead mother, by the Cæsarean operation, thirteen minutes after the maternal circulation had ceased. And instances where living children were extracted in this way within ten minutes after the mother's death are not rare. It is probable that no part of the foetus is supplied with pure arterial blood, and on this account it may be able to live longer shut off from the air than it would be if deprived of oxygen after respiration was established.

But it must be remembered that this is not independent life, for it is still living upon that which it has received from the mother. As yet, the child cannot participate in a single interest common to mankind; there is nothing of this world that it can partake of, not even the atmosphere we breathe; and it is as dead to all such interests as if it were still unborn. It is a prolongation of foetal life, likened by the plaintiff's counsel in "the Delaware case" to the momentum imparted to a piece of machinery and retained for a while after the impelling power had been withdrawn. A better illustration, however, might be found in a locomotive which, with steam in the chambers and fire in the furnace, escapes

* In confesso est respirationem a vita et vitam a respiratione separari non posse, adeo ut vivens omnino spiraret et spirans omnino vivat.—GALEN. Life means respiration; not to have breathed is not to have lived.—CASPER, vol. iii. p. 33.

from the depot without fireman or tender. Although it is cut off from the source of its supplies, it will continue to run so long as a sufficient amount of steam is generated by the fire within it. It is alive, so to speak, but in the condition of a child that cannot breathe. No fuel can be supplied, the fire must go out, motion cease, and the engine remain an inert mass upon the road.

With the exception of respiration, there is no phenomenon we can adduce to show the difference between foetal and independent life; and this is one of such a positive character, and attended with such prominent physiological changes, that I cannot do otherwise than accept the statement of Drs. Ramsbotham and Lee, "Nothing less than breathing can establish the fact of a live birth." I do not understand these gentlemen as admitting that a child is dead because it does not immediately breathe after its birth. "The fallacy of this opinion" is undoubtedly shown in the case quoted by Dr. Reese, where the infant commenced breathing after restorative measures were used. But in the Delaware case it was otherwise, for the child failed to respond in any way to the remedies applied by skilful physicians. And may we not argue that their want of success exhibited "the fallacy of the opinion" entertained by those who declared it to be alive?

Is the *beating of the heart* a satisfactory evidence of life, sufficient to establish its existence both physiological and legal? Temperature and muscular movement are also indicative of the presence of life, but, confessedly, not always reliable. Sometimes the fibres of a muscle have been noticed in rhythmical motion, so that "a sensation as of the pulsation of an artery was plainly felt" when one's fingers were pressed upon it (Carpenter's Phys.). Dr. Brown-Séquard "has observed some curious rhythmical movements, from five to twenty in the minute, in the intercostals, diaphragm, and some of the muscles of locomotion, after death." How readily an inaccurate observer might mistake this motion of the intercostals for that of the heart! and how much more easily one may be deceived when searching for that which is ardently desired!

By an English court, many years since, the tremulous motion of an infant's lips, in the absence of all other indications of life, was considered sufficient evidence to establish the fact of a live birth. But that decision would not hold good now, for we know that muscles do not lose their irritability immediately after death. And the heart itself,—the most irritable of muscles,—may it not throb after an individual has ceased to live? In some instances the heart will continue its pulsations long after the animal is dead. In animals killed with conium it will beat for many minutes after death (Dr. William Curtis, in *New York Medical Record*, May, 1875); and the frog's heart, even when it is cut into slices, will continue its rhythmical motions. It is true that the life of the body is dependent upon the functional activity of the heart in common with that of other organs; but does it follow that it must stop beating before we can say, "He is dead"? The hanging murderer is not cut down until the heart-

beat is no longer detected; but is he—the murderer—not dead before this?

One would not be apt to regard a headless body as a living being, yet it is on record that the heart of a decapitated criminal was seen pulsating twenty minutes after death, and continued with perfectly regular action, at the rate of forty-four pulsations in the minute, for an hour (Carpenter's Physiology). Was this "a satisfactory evidence of life sufficient to establish his existence, both physiological and legal"? Many cases might be cited having a tendency to lessen our faith in the reliability of this sign of life, but none of them are so remarkable as the one which I will give on the authority of my friend Dr. Renel Stewart, of this city, who has promised to report it to the *Times*.

In July, 1872, at 10 o'clock P.M., he was called to a neighboring house, in which he found a gentleman pulseless, cold, and stiff. The jaw had dropped, the eyes were fixed; in fact, every indication of death was present, and, as a matter of course, the doctor pronounced him dead. Happening to place his ear over the cardiac region, he detected the beating of the heart. There was no mistake in this, for by manipulating the chest its action became stronger, and he succeeded in obtaining a radial pulse. Cadaveric rigidity had set in, and he could raise the entire body by its head. Dr. S. visited the house at intervals until seven o'clock in the morning, and at each visit ascertained that the heart *was still beating*. At eight o'clock it ceased to beat, relaxation had occurred, and symptoms of decomposition were plainly discernible.

The points I wish to illustrate by this article are as follows:

1. The law, reasonably interpreted, demands more than "simply proof of life" in the issue before it can be called living.
2. That the proof of respiration was originally necessary to establish a live birth, and that there is no evidence to show that this proof is not still required.
3. That until respiration occurs the life of the child must necessarily be considered as foetal.
4. That the law, reasonably interpreted, cannot recognize a foetus as living issue. It must be born with a possibility of inheriting, which possibility fails if it lacks at its birth the functions of independent being.
5. That respiration is the only evidence of an independent life.

SYPHILITIC SEMEN.

BY ISAAC SMITH, JR., M.D.

ASK the indulgence of the readers of the *Times* for the further consideration of the question, Is semen of a syphilitic patient a vehicle of infection? which was raised by my report of a case in the November number of the *New York Medical Journal*, page 499. This question, which has been so ably, impartially, and scientifically discussed by R. W. Taylor, M.D., in the pages of the *Times*, February 27, demands all the light that can be thrown upon

it, and that is available and germane for its proper illumination, and this is my apology for this communication.

In my original paper, some points, although thoroughly weighed in my own mind, were inadvertently omitted, which I will try to introduce now; should I fail, however, to do so satisfactorily, I shall be pleased to answer any question pertinent to the subject.

My patient is of a nervo-sanguineous temperament, and hence was often under inspection. He was ever on the alert for breakers. This causes me, naturally enough, it must be conceded, to speak with more assurance than I should be justified in doing in ordinary cases of syphilis. His penis was normal in every particular prior to infection. I have never seen any solution of the continuity of any part of it, or of the chancre-cicatrix, other than the initial lesion and the later chancre alluded to. He had "travelled" so much previous to marriage that no stress could be laid upon the ardor of being "newly married." I apprehended no danger of abrasions, consequently no "necessity to warn" my patient of the possibility of infection by such accidents.

He never had mucous patches or lesion of any of the mucous surfaces until nearly two years after the date of invasion, and then had what was described by me as a urethral chancre, a re-inoculation as I considered it at the time. I have not the slightest evidence that any abrasion of the penis occurred; hence, no point that the wife was syphilized by inoculation of his blood. If an abrasion occurred, it must have been microscopical. It is, under the circumstances, obviously impossible to say positively and finally that he did or did not thus infect her. What stretch of the imagination or of the truth, I submit, does it require for me to sum up that he did not thus infect her, when I only have a possibility, but not a probability, of such inoculation? If that source of contamination has been eliminated, it brings us again to the original "hypothesis," that of syphilitic semen.

Now, then, if the semen of a syphilitic man will impregnate a healthy ovum, and, later, that fertilized egg will infect the mother, does it not seem logical as well as reasonable that the syphilitic germ was present in the semen? and in this case, that element being present, why could it not contaminate a "uterus very susceptible to the transmutation of fluids"? Surely the mathematical proportions of a spermatozoon could offer no very insurmountable obstacle to transudation, and as surely it seems that it might follow where a blood-disk leads into the circulation.

The following lines extracted from a lecture on life and on vital action, by Prof. Lionel S. Beale, M.A., F.R.S. (*London Lancet*, May 15, 1875), may not be uninteresting in this connection:

"The bioplasm of a human spermatozoon, which, perhaps, hardly weighs as much as the one-hundredth part of a single red blood-corpuscle, may stamp with unmistakable individual characteristics several tissues and organs which in their fully developed state weigh many pounds." Again he

says, "Here is one of the very smallest living particles carrying the most extensive powers,—powers which may reach to every tissue in the being that is to be formed. It is, nevertheless, suggested that the spermatozoon may be composed of millions of particles, one or more having been detached from every component element of the tissues of the parental organism. But this is not all; for every one of millions of spermatozoa must be considered as having been formed in the same way."

From what I have written upon this case, is a physician warranted and blameless (should subsequent infection follow) in advising a syphilitic patient, who presents no visible signs of the disease, that the only danger of infecting his wife will occur either from pregnancy or abrasion of his penis? May I ask Dr. Taylor if he would feel secure in so teaching a patient?

FALL RIVER, MASS., June 8, 1875.

A COMPLICATED TWIN LABOR.

BY H. G. LANDIS, A.M., M.D.,

Niles, Ohio.

AT 11.45 P.M. of November 5 I was called to deliver Mrs. S., æt. 29, fourth pregnancy, in labor since 8 A.M. An illiterate midwife in attendance had become alarmed at an unusual delay,—viz., the child's head had been born for an hour, and there was as yet no inclination of the body to follow, although the pains were powerful. On introducing a finger into the vagina in search of an axilla, a second head was found on the pelvic floor, in immediate contact with the thorax of the first child, and in a directly transverse position; the anterior fontanelle being nearly opposite and below the right tuber ischii, the posterior fontanelle a little below the left tuber. The anterior and already born head was covered by very thick membranes, which were divided by scissors and peeled back. During several pains this head was observed to be immovable, not inclined to yield to traction; neither could the posterior head be pushed upwards, but was perceptibly driven towards the outlet. Following this indication, two fingers were inserted in the vagina as far as possible, and the perineum drawn down during a pain; at the same time the anterior head was pulled forwards and up over the pubes. The second pain brought the posterior head so far down that it could be seen with the same membranes as tightly stretched over it as with the first head. These were again divided, and the succeeding pain drove the second head through the vulva; the rest of the child followed at once, and was followed by the anterior child. The placenta came away with light traction in six minutes. It was large, with two separate cords; the chorion and amnion were common. The children were both female, of the same size, and weighed each five pounds. The second head measured four and a half inches in the occipito-frontal and three and three-quarter inches in the bi-parietal diameter. In passing down it had pressed a groove in the chest of the first child, the sternum being flattened against the

vertebræ. If the vagina had been less capacious, dismemberment and evisceration of the anterior child might have been necessary. The second child is living and hearty at this date, and the mother made a good recovery. This accident seems to be rare, and, indeed, incredible if the case were under professional guidance from an early period of labor. Neither Cazeaux nor Meadows mentions it; Churchill records similar cases, and Leishman mentions it fully.

POISONING BY RHUS RADICANS.

BY S. W. MORRISON, M.D.

I HAVE used with entire satisfaction for some three years or more, in the treatment of the eruptions caused by rhus radicans, the prescription which I give below. In many trials I have never seen it fail, no matter in what stage of the disease it has been applied, to relieve and check the inflammation immediately. I have never known it to be used by any other person; and as this is the season when abundant opportunity is afforded for trial, I hope it may be made, and that we may have the results through the *Medical Times*. I do not know that the sulphite of sodium is of any use in this prescription, but I know that it will not be of much use without the carbolic acid.

R Acid. carbolic., f3ss;

Sodii sulphis, ʒiij;

Aquæ font., f3vj.—M.

S.—Apply continuously to the parts affected, on bandages of muslin.

NOTES OF HOSPITAL PRACTICE.

KING'S COLLEGE HOSPITAL, LONDON.

SERVICE OF MR. JOHN WOOD, F.R.S.

Reported by JOHN B. ROBERTS, M.D.

PLASTIC OPERATION FOR THE RELIEF OF EXSTROPHY OF THE BLADDER.

A BOY, aged about two years, was the subject of a congenital malformation of the pubes and bladder, which, on account of a deficiency of the symphysis and rami of the pubes, allowed a hernial protrusion of the posterior wall of the bladder through a fissure extending nearly up to the umbilicus. The back of the bladder, pushed forward by the pressure of the intestines behind, forms a tumor in the hypogastrium, which is red, because the mucous membrane of the internal surface of the bladder is seen as the viscus is everted. If the penis be raised up, the internal orifices of the ureters are seen as they enter the bladder, and the urine can be observed dropping from them. Whenever the child cries, the pressure of the diaphragm causes the bladder to protrude further, and thus the tumor increases in size.

From the friction which must necessarily be received from the clothing and limbs of the child, the mucous membrane has become inflamed, and is secreting mucus and pus. This causes a great deal of pain, which is aggravated by any movement; and another source of greatest discomfort is the continuous escape of urine upon the surrounding parts.

For these reasons an attempt shall be made to relieve the child by a plastic operation, whereby the tumor shall be covered by skin to prevent friction, and subsequently the epispadic condition met by taking integument from the scrotum.

The tumor is covered by taking first a curved tongue-like flap from the belly, above the everted bladder, and this is turned down with its epidermic surface towards the mucous membrane of the bladder, so as to cover the opening through which the protrusion occurs. Then a flap is dissected from the groin on each side, and these two flaps drawn towards the middle line, where they are brought together over the *turned-down* superior flap. By this method there are placed three thicknesses of integument over the abnormal opening, which not only relieves the sensitive mucous membrane of friction, but affords support, and prevents the protrusion of the bladder by the intra-abdominal pressure. In some cases the success has been so great after this operation that there has remained only a small opening, and the patient has been able to go all night without wetting the bed.

In making the superior flap, care must be taken that it be sufficiently long to allow for shrinkage, for it is wanted to come down nearly, but not quite, to the penis; another precaution is to cut very carefully when dissecting up its base, for the skin and belly-wall are thin just above the bladder, and the knife, by an unlucky stroke into the peritoneum or subperitoneal tissue, may cause much damage by rendering the patient liable to peritonitis. Not that the mere wound of the peritoneum is to be feared so much, but the urine, with which the parts are apt to come in contact during the progress of the case, will cause inflammation of the peritoneal membrane and insure a fatal result, as has happened when sufficient attention has not been paid to this source of danger. This flap depends for its vitality on the corners running alongside of the bladder, and care should be exercised in cutting here, in order that sufficient nutrition be allowed to prevent sloughing.

The flaps taken from the groins are somewhat lancet-shaped, but with a blunt point, however, and get their nourishment from the superficial branches given off by the femoral artery in the neighborhood of Poupart's ligament.

The three flaps are now dissected up, and it remains to place them in position by sutures. Before doing this, the parts are cleansed of clotted blood, and the bleeding entirely stopped by a sponge and cold water, because after the hemorrhage is arrested a gluey substance exudes, which sticks the flaps together like two pieces of wet paper, and thus prevents the urine being infiltrated between them. This is an important point in the operation.

The protruded bladder having been pushed back by the finger of the operator, the upper flap is turned down over the aperture (the flap has no hairs on it), and then the side-flaps drawn over it without being turned, so that there are two raw surfaces in apposition. Sutures are applied by passing four long pins through the opposed edges of the lateral flaps, including, as they are pushed through, the upper part of the superior flap, but not passing through it to the other side, for that would allow the urine to work its way between the flaps. All these precautions for keeping the parts as free as possible from contact with the urine are important, for there must be at times gushes of urine from sudden movement on the part of the patient. The pins are wrapped with a ligature twisted around like a figure 8, and passed from one pin to another.

It now remains to bring together the parts from which the skin-flaps were taken; and to do this the thighs are flexed, to relax the integument as much as possible.

The wound above is drawn together by hare-lip sutures, to afford as great support as practicable, and to endeavor to obtain immediate union, which, by the way, is not nearly so necessary here as below; but at the sides wire sutures are used, because of the fold of the groin interfering with the placing of the pins. If care be not taken in the proper disposition of the sutures at the corner, the urine will find its way through, and there will be left a sinus.

This is the eighteenth or twentieth case of congenital malformation of this kind that Mr. Wood has operated upon, and generally he has had excellent results from this mode of proceeding. Fatal issue may sometimes occur from disease of the kidney, induced by extension of inflammation from the mouth of the ureters to the pelvis of the kidney, and by the obstruction at the orifices of these ducts, as in one of his cases, where, after death, the autopsy revealed cystic degeneration of both kidneys.

After oil has been applied to the wound, the knees are tied together, with cotton between them, and a bandage passed around the shoulders and legs, in order to keep the little patient in a crouching position to relax the parts and prevent tearing out the sutures. This position shall be maintained more securely by propping him with pillows, and it will be necessary to keep him from crying or coughing, because the intra-abdominal pressure is increased by these acts and great strain brought upon the sutures.

When the child gets older, an attempt shall be made to improve the condition of the urethra by taking skin from the scrotum, after a modification of the operation devised by Nélaton for these cases. It will be better, however, to wait until the penis and scrotum are better developed.

TRANSLATIONS.

THE ACCIDENTS OF CONVALESCENCE have been deemed of sufficient importance by Dr. Rathery to form the subject of a thesis. According to this gentleman, these are numerous and various. He divides them into troubles of the nervous system, of the digestive tube, of the genito-urinary apparatus, of the functions of the skin, etc.

Under the first head are comprised disturbances of intelligence, motility, sensibility, and mixed troubles. Delirium in its various forms, vertigo, cephalalgia, are among those most frequently encountered under the first subdivision, while among troubles of motility paralysis is the most important. In addition, however, convulsions, trembling, and contractions are met with, and to these Dr. R. devotes a chapter containing much that is interesting and new.

Among troubles of the digestive apparatus which may retard convalescence, ravenous hunger, or, if this is satisfied, weight in the stomach, abdominal distention, and flatulence, may be mentioned. In addition, laborious digestion and diarrhoea are not uncommon.

The accidents which may attack the respiratory tract during convalescence are not numerous. Laryngeal necrosis is occasionally observed after typhoid fever.

As to accidents of the circulatory apparatus, these may be divided into central disorders, as palpitations, etc., and peripheral, the principal consequences of which are dropsy and gangrene of the extremities. If in addition to the above we mention troubles of the genito-urinary functions, albuminuria, and the like, and troubles of the skin, desquamation and certain erythematous and papular eruptions, we shall have pretty much covered the ground gone over by Dr. Rathery. The work terminates by some general considerations,

together with the various therapeutic indications, and has a certain value on account of the novel point of view, and also as drawing attention to a frequently neglected portion of the physician's duty,—the guidance of convalescence.—*Le Progrès Médical*, May 1.

A CASE OF HEMIPLEGIA FROM LIGHTNING-STROKE.—A signal-man on one of the German railways had occasion to wind a clock connected with the telegraph during a thunderstorm. At the moment when his *left* hand was on the key, a flash of lightning struck the wires, and from thence passed to the clock, the key, and the patient's hand and arm. He fell to the ground, senseless, but was awakened an hour or so later by the rain pouring upon his face, and managed to drag himself home. Examination showed abolition of motility in the upper and lower extremities on both sides, as well as decided diminution of sensibility. During the following days the patient suffered from severe pain in the head, sleeplessness, dizziness, and muscular tremor. At first there was retention of urine and fæces, the bladder having to be emptied by catheterization. These symptoms gradually disappeared, though the patient complained for some time of a feeling of pressure on the chest. Under the use of electricity the patient gradually recovered in a very considerable measure the use of his limbs. Dr. Eulenberg, who reports the case in the *Berliner Klin. Wochen.*, April 26, gives very full notes of the symptoms, and believes the lesion to have been a hemorrhage in the region of the corpus striatum. It was a curious circumstance (which Dr. E. discusses at length) that the lesion occurred on the opposite side of the brain to that which should theoretically have been affected.

ACNE OF THE PHARYNX, ETC.—M. Isambert, in a clinical lecture on disease of the larynx and pharynx published in *Le Progrès Médical*, May 15, speaks of acniform angina as follows: Three principal varieties have been described:

1. Simple acne, characterized by red prominences, which may suppurate or even ulcerate. The accompanying sensation is that of tickling, which provokes coughing and hawking. This form is coincident with facial acne.

2. Pustular acne is situated principally upon the tonsils. Two or three glands only are attacked at a time. It is, in fact, an inflammation of the cryptic glands of the tonsil, with hypersecretion of caseous matter, and, occasionally, encystment of cretaceous calculi.

3. The third form is acne indurata, due to hardening of the glandular exudation. The elimination of this secretory product is followed by ulcerations, which often unite and give the appearance of a honeycomb to the surface.

Although but few observations upon this form of acne have been made, yet it seems probable that this affection is not unusual, and is similar in all essential respects to the same disease as it appears on the external skin.

EPILEPSY—CURE FOLLOWING A WOUND.—Dr. R. Blache reports the following case (*La Tribune Méd.*, May 16).

A boy of eleven was attacked by epilepsy, the fits coming on at first twelve and then eight days apart. Bromide of potassium was prescribed, but was not followed by any amelioration of the symptoms.

One day, while cutting wood, the patient chopped off the extremity of the left middle finger, the incision passing through the middle of the nail. For two hours the unfortunate individual uttered cries of anguish, and was extremely excited. At the end of that time the wound was dressed; it healed kindly, and no return of the epileptic attacks occurred.

DIFFERENT EFFECTS OF PEPSIN.—Dr. Dettmar Finkler (*Archiv für Physiologie*) has made some digestive experiments to discover the explanation of the points of difference between the views of Ernst, Brücke, and George Meissner.

He found when coagulated albumen was allowed to dissolve at the proper temperature in the juice expressed from a pig's stomach, taken as fresh as possible, acidulated with hydrochloric acid, that no evidence of the existence of parapepton was obtained, on following the plan recommended by Meissner; although a satisfactory response followed the application of the test when the digestive fluid was made from commercial pepsin (*pepsinum activum*) instead of the recent juice. In this last solution the other reactions were obtained also, which Meissner thought were caused by the presence of metapepton, and a-, b-, and c-pepton. Increasing the quantity of the pepsin used did not diminish the amount of the precipitate on neutralization.

It may be proper to add that in the first solution, *before the albumen was completely dissolved*, a precipitate was obtained when a portion of the fluid was neutralized by caustic soda, but not after the albumen had disappeared and the solution became clear.

He therefore thinks that the physiological digestive process has been correctly recognized by Brücke.

W.

THE ANTISEPTIC TREATMENT OF MASTITIS BY LISTER'S METHOD.—E. Heyder (*Centralblatt für Med. Wissen.*, No. 19, 1875) describes the method usually employed in Bardeleben's clinic. When, in spite of ice-bladders and support, an abscess has developed in the mammae, he washes the surface with a one-and-a-half per cent. solution of carbolic acid, and then under the carbolic spray he makes an extensive incision and opens a way out for the pus by the finger. Subsequently, counter-openings are made, and drainagetubes placed in each opening. Compresses of lint and gauze are placed over the wounds, and the whole is kept in place by a gauze bandage. All dressings are soaked for three hours in a five per cent. carbolic acid solution, and then preserved in a one-and-a-half per cent. solution. After twelve hours the second dressing is applied over the other, consisting of several gauze compresses, the outer one covered with a piece of rubber cloth. The dressing is not again changed until the secretion soaks through. The author's preference for this method is based upon the fact that the fever quickly abates after the incision has been made, the secretion of pus can be restrained, and the cure is accomplished in from eleven to fifteen days. New abscesses seldom make their appearance. The author recommends the procedure for private practice, being quicker and more convenient than that ordinarily used.

X.

GLYCOGEN IN THE LIVER AFTER LIGATION OF THE DUCTUS CHOLEDOCHUS.—V. Wittich (*Centralblatt für Med. Wissen.*, No. 19, 1875) has ligated the bile-ducts in pigeons and rabbits, and, collecting the excretions, has examined them as well as the livers of the animals by a process of which the outlines are given in his communication. Comparison of the results with those obtained by examination of healthy livers shows a marked diminution in the glycogen after ligation of the bile-ducts. Wittich suggests that this may be explained by supposing either that the glycogen in the liver is more rapidly converted into sugar and carried into the circulation in presence of the retained bile, or that the liver, interrupted in its secretion, produces no more glycogen than that which is present at the time. The latter view would more easily explain Wickham Legge's experiments, though these contradict Wittich's observation of spontaneously appearing melituria, as well as the

observations of other authors in regard to the appearance of sugar in the urine after any irritation of the liver.

X.

THYMOL—A NEW ANTISEPTIC.—Dr. L. Lewin sends a communication to the *Centralblatt für Med. Wissen.*, No. 21, 1875, on the subject of thymol, a benzole occurring in white, aromatic crystals, soluble in hot water in the proportion of 1 to 1000, and having in solution a neutral reaction.

A comparison instituted between thymol and salicylic and carbolic acids, as to their relative effect in retarding fermentation, resulted in placing the former at the head of the list, it showing twice as great anti-fermentative effect as carbolic acid, and four times as great as salicylic. Similar results were shown in mixing the thymol solution with putrid matters, this substance showing marked antiseptic properties.

Although thymol itself is expensive, yet it acts in so dilute a solution as to render it in fact cheaper than either carbolic or salicylic acid.

Dr. Lewin promises further particulars in regard to the new disinfectant, with which he is experimenting extensively.

X.

XERODERMA (SCLERODERMA? Tr.).—The following case is reported in the *Allg. Wien. Med. Zeit.*, 1874, 35, by Dr. I. Glax.

The patient, a female, 26 years of age, had had, even in childhood, an inelastic skin. After an attack of articular rheumatism, occurring in her twenty-second year, she experienced a difficulty in moving the extremities, the skin became cool, and the face stiff. The skin appeared in some places thin and parchment-like, and somewhat pigmented. The integument of the extremities was stiff and like marble. The fingers remained immovable in a semi-flexed position. Nothing else abnormal was observed. Dr. Glax hoped by inhalations of amylic alcohol and administration of whisky to bring about enlargement of the minute arteries, and, as a result, greater succulency of the tissues with secretion of sweat. While, however, the symptoms of xeroderma were disappearing under this treatment, the patient went from under observation, and the result remained, unfortunately, unknown.—*Centralblatt*, No. 19, 1875.

X.

GLYCERIN IN THE TREATMENT OF DIABETES.—M. Garnier has addressed a note to the Académie des Sciences on the employment of glycerin in the treatment of glycosuria. M. Schutzen, of Dorpat, has shown by his researches that glycerin either alone or associated with tartaric acid, and taken in the dose of half an ounce to an ounce and a half in the course of twenty-four hours, constitutes a valuable adjuvant to the régime especially adapted to glycosuria. M. G. has himself made use of purified glycerin, and has made it more palatable by mixing it with a certain amount of alcohol and of aromatic substances (mint, anise, bitter orange). The employment of glycerin has aided him greatly as well as other patients.—*Bull. Gén. de Thérap.*, No. 10, 1875.

TREATMENT OF CAVERNOUS ANGIOMA WITH GALVANO-CAUSTIC PUNCTURES (E. Tünger: *Centralblatt für Chirurgie*, No. 22, 1875).—The method of treatment here described is one of which Thiersch availed himself in a case of extensive cavernous angioma. A metallic plate in which there are numerous perforations, through which a straight metallic instrument suitable for the formation of fistulae can be passed, is pressed upon the tumor. The advantages claimed for the procedure are that if the clamp is allowed to remain upon the tumor for half an hour after the operation, there is no hemorrhage, the reaction is but slight, and the time requisite for healing short.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 3, 1875.

EDITORIAL.

WOMEN IN MEDICINE.

A CHRONICLER of the passing events of the day cannot fail to note the continued growth of the "woman movement" in medicine. Abroad, Mrs. Garrett Anderson appears to be received freely in the best medical circles of London; at home, we have the president of our State association congratulating the society on the establishment of our Woman's Medical College; in New York a woman presides, or has presided, over the county medical society; and in Boston the Medical Journal lavishes praise on Miss Susan Dimock, who was lost in the *Schiller*. As we said some time since, the day for discussion is over; and, although the brain of the average woman does weigh less than that of the average man, and although some may believe the profession is being deteriorated, going to ruin, or what not, yet it is becoming more and more apparent that, like the negro at the South, woman in medicine is a fact which it is wiser to adapt ourselves to than to knock out our brains against.

There is one position of usefulness which all of us are probably willing medical women may fill, —i.e., physicians to the zenanas of India. A number of women, all of them more or less thoroughly educated in medicine, some of them thoroughly cultivated and refined, have already been sent to that country from the United States. Penetrating into families where it would be impossible for a man to enter, carrying healing in one hand and the Bible in the other, they have already done great

good, and are becoming a most efficient power in overthrowing the abominable customs of heathendom.

The whole policy of the India government towards missions has, of late years, been reversed: formerly it was even actively hostile, now it is actively friendly,—a change probably due to the recognition of the fact that India can only become English by first becoming Christian. Probably from seeing the good which is being accomplished by the female medical missionaries, the India government has decided to encourage the medical education of women, and has opened the Madras Medical College to them. Indeed, while the unfortunate wearer of pantaloons has to pay heavily for the privileges of the lecture-room, the whole course is given gratuitously to any capable wearer of petticoats. The course of study is three years; with the exceptions of obstetrics and surgery and one or two lectures in anatomy and physiology, the female students are required to attend with the male.

SCHOOLS FOR MIDWIVES.

THERE lies on the table before us the circular of the "St. Louis School of Midwives." This institution, which claims to be, and we presume is, the only one of the character in this country, has been in existence in one form or another since 1854, and has not, therefore, found many imitators. Possibly as "Mrs. Carpentier's School of Midwives" its character was such as to make it love darkness better than light. Of this, however, we have no knowledge. With Dr. George J. Engelmann as its director, the institution certainly challenges thoughtful attention. Either such schools ought or ought not to exist. If they are baneful, it ought to be known; if they are useful, St. Louis ought not to hold the monopoly. The object of present writing is not to praise or to criticise, but if possible to call out discussions from those better informed upon such subjects. At first view, it seems to us that such "schools" are injurious, and will become the mothers of the worst form of quackery; but we may be mistaken. To make the matter clearer, we append the following extract from the circular itself:

"The wives of laborers and mechanics, when about to become mothers, are wont to trust their lives in the hands of midwives, the English-speaking of whom are mostly wholly uneducated and totally incapable women; and now, as the population of our city is rapidly increasing, the proper instruction of such midwives becomes a most important matter.

"There is great need of educated English-speaking

midwives, not only in this city, but throughout the entire country, and it is the object of the St. Louis School of Midwives to educate capable and conscientious women to supply this demand, to give to the women of the working classes better help in their hour of trial.

"We shall award our diploma only to such as are qualified and fit to discharge their important duties. We shall graduate midwives who are competent to conduct natural labor cases and will not go beyond this; who are able to detect any deviation from the ordinary course of labor, any threatening danger, at an early period, in order that medical assistance may be called in time. We shall not graduate female physicians or women who will in any way dabble in medicine."

All this may appear very reasonable; but is it not rather absurd to suppose that the school can control its graduates so that they shall not dabble in medicine? So far as concerns this part of the country, the wives of laborers and mechanics, at least of the English-speaking races, are not wont to trust their lives to midwives; but it is barely possible the introduction of such ministers of good might be a good—or might be an evil. Which would it be?

LEADING ARTICLE.

THE DISCUSSION ON PUERPERAL FEVER IN THE LONDON OBSTETRICAL SOCIETY.

THE proceedings of the great London medical societies have been enlivened of late by discussions on general medical subjects. It was complained some time ago that "the continual passing around of livers on soup-plates" at the Pathological was becoming monotonous, and the suggestion was made that this time-honored procedure should occasionally be varied by discussions on questions connected with general pathology. The idea found favor, and one of its first fruits was the well-remembered debate on the relation of tubercle to phthisis, which was carried on by distinguished members of the Society, and attracted general attention. It was followed by discussions upon cancer, and recently upon the germ-theory of disease. The Clinical Society also adopted the idea, and the debate upon pyæmia which resulted attracted no less attention than did those of the Pathological. Now we have the Obstetrical Society following the fashion in a discussion upon puerperal fever, a discussion claiming attention not less from the character of the participants than from its intrinsic interest. On the first evening upon which the subject came up for discussion, Mr. Spencer Wells opened the debate with a series of propositions or questions essentially as follows: Is there such an entity as puerperal fever? or may all the forms of fever known under this name be referred to the attacks of some well-known continued fever, as scarlet fever on

the one hand, or on the other to some surgical fever, as erysipelas, pyæmia, or septicæmia? Assuming such a disease, how can its spread in private and hospital practice be most certainly prevented or checked? In conclusion, what relation have bacteria and allied forms to the pyæmic process in the puerperal state, and what is the value of antiseptics in the prevention and treatment of puerperal fever?

In the very interesting address with which he introduced these propositions, Mr. Wells showed himself emphatically opposed to the idea of the existence of such a disease as puerperal fever, the process usually known by that title being only a modified form of one of the affections above mentioned. As regards the nature of the contagion, he expressed himself in favor of the germ-theory, and advocated the use of antiseptics. Finally, he urged that if pyæmia and traumatic fever can be kept out of a surgical hospital, there is no reason why puerperal fever should not be kept out of a lying-in hospital.

Drs. Leishman and Braxton Hicks continued the discussion. The former contented himself with the consideration of the identity of puerperal fever with the various other affections alluded to. He agreed in the main with Mr. Wells, but believed in some special condition in the puerperal state which favors the occurrence and intensifies the malignancy of intercurrent affections.

Dr. Hicks expressed views similar to those of Messrs. Wells and Leishman, but gave a very doubtful assent to the bacteria-theory.

Mr. Jonathan Hutchinson, regarding the subject from a surgical point of view, expressed himself opposed to the idea of a specific poison which can produce any fever which should be known as puerperal fever.

Dr. Richardson, who closed the discussion, maintained that a woman after delivery was just in the condition to be the subject of a series of changes which must be febrile in character. He agreed with the previous speakers in rejecting the notion of a special poison belonging to the puerperal state, as well as that of the existence of such a disease as puerperal fever. As regards the germ-theory, he was opposed to this and in favor of the purely physical theory of contagion. Antiseptics he thought useful, not because they destroy the germs, but because they interfere with the poisonous action of the septicæmous material which produces the fatal disease. Finally, Dr. Richardson made the cheerful prediction that within ten years some method of preventing these diseases would be discovered, which should be as certain as vaccination against smallpox.

It will be seen that thus far but little has been gained by the debate. The gentlemen who took part in it seem generally agreed as to the non-existence of the disease under discussion; some have also expressed their adherence to the germ-theory of disease, others have opposed it. This seems to be the essence of what has been gained. The whole debate would appear from the report to have been rather of an impromptu and extempore character, scarcely worthy of the subject and the Society. We must except from this Mr. Wells's

address and formulated propositions, which, if followed strictly, would perhaps have resulted in more light being thrown on the subject than has been the case.

As the discussion has not yet been closed, but only adjourned, we may hope to have more facts and figures and fewer anecdotes from future speakers.

CORRESPONDENCE.

Boston, June 10, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—A year ago it was my privilege to send you an account of the Annual Meeting of the Massachusetts Medical Society. During the past two days the yearly reunion has recurred. It seems to be the general opinion of its members that the Society was never in a more flourishing condition than at present,—a prosperity due in no small degree, as I learned from gentlemen from various parts of the State, to the efficient administration of affairs during the past year by the President, Dr. B. E. Cotting.

On Tuesday, at 10 o'clock A.M., there were operations and surgical visits at the Massachusetts General, the City, and the Carney Hospitals.

Last year I reported concerning the two new wards that had been erected at the first-mentioned hospital. So much satisfaction was given by them that since that time the trustees have erected a third new building, the Bigelow Ward, which is thought to present some improvements upon those erected two years ago.

The grounds about the City Hospital are in a state of considerable confusion, in consequence of the laying of foundations for new structures. The city government has appropriated \$190,000 for the purpose of furnishing increased accommodations and facilities for the institution. There are to be four new pavilions,—two for surgical and two for medical cases,—a new amphitheatre, accident-room, etc., on the first floor, and various other additions, which it is hoped will be in working order by the time of the next annual meeting, and which will nearly double the capacity of the institution, so that it will furnish four hundred beds to patients.

At 12 o'clock M. the Society met in the Hall of the Lowell Institute, to listen to the reading of papers. The first paper was by Dr. R. T. Edes, of Roxbury, "On the Treatment of Typhoid Fever by Cold Water." The writer stated that the use of cold water in the disease under discussion was not a new remedy; that its success must not be judged of *a priori*, but by experiment. Sponging and packing are not so useful as the bath. A full bath, at the temperature of the body at first, and gradually cooled, is to be taken. Meanwhile, the patient's extremities are to be rubbed, and wine is to be administered. The employment of stimulants is of importance in almost every case. The bath is to be repeated as often as the patient's temperature becomes excessive,—often five or six being given in twenty-four hours. Dr. Edes thinks that statistics show a fall-

ing off in the mortality of typhoid fever from the use of baths. His own experience extended to sixty-six cases, of which eleven proved fatal.

The paper was temperate in its character, and moderate in its advocacy of the treatment proposed. In view of the acknowledged difficulty of properly carrying out the method, it would seem hardly probable that, except in hospitals, the treatment of typhoid fever by cold baths will ever be much practised unless results much superior to those of other methods can be shown for it.

Dr. G. E. Francis, of Worcester, next read a paper on "The Obstetric Forceps as a Time-saver." He laid it down as an axiom that mortality in labor increases in proportion to the length of the labor,—this of the second stage. Accordingly, we ought to shorten the latter as much as possible. The forceps are the means of attaining this end, and we should use them before the patient's strength is exhausted. In the last three hundred cases which had occurred in the reader's practice, he had used the forceps fifty-one times. He had followed the rule of not waiting longer than two hours after dilatation of the *os uteri* before applying them.

A paper on "The Microscopy of the Urine" was presented by Dr. G. H. Pillsbury, of Lowell. Its object was to urge the use of the microscope, whose revelations are much more satisfactory than those of chemistry, for the discovery of abnormal matters present in the urine, and to dissuade the minds of his hearers from the idea that the employment of the instrument requires a skill attainable by but few, or that an expensive instrument, and one of very high power, must be employed in an examination sufficiently accurate for practical purposes.

Dr. Leonard Wheeler, of Worcester, followed with an essay on "The Inner Surface of the Uterus after Parturition." He stated that during pregnancy the connective tissue of the uterus enormously increases, and the epithelial covering mostly disappears. After parturition there is a wounded surface composed of connective tissue well fitted, apparently, for resorption of different substances into the blood or lymph system. The method of the process of renewal of the epithelial lining is difficult to determine. The process seems to be one of fatty degeneration of the lining tissues of the uterus, and the products of this degeneration form a part of the lochia. An epithelial layer gradually forms, most slowly over the placental site.

Dr. F. W. Russell, of Winchendon, followed with a long paper on "Alcohol in some of its Pathological and Social Relations." A minute description was given of the effect of alcohol on the different tissues. The various forms of aberration of the intellect due to the abuse of alcohol were considered. The reader criticised the idea of trying to reform drunkards after diseased action is set up.

In the evening the annual meeting of councillors was held, at which the following were chosen officers of the Society for the ensuing year:

President, Dr. B. E. Cotting, of Roxbury.

Vice-President, Dr. Joseph Sargent, of Worcester.

Treasurer, Dr. F. W. Draper, of Boston.

Corresponding Secretary, Dr. C. W. Swan, of Boston.

Recording Secretary, Dr. F. W. Goss, of Roxbury.

Librarian, Dr. D. H. Hayden, of Boston.

Dr. P. Le B. Stickney, of Springfield, was appointed Orator, and Dr. J. H. Mackie, of New Bedford, Anniversary Chairman for the next annual meeting.

At 10 o'clock P.M. the Society re-assembled in the Lowell Institute to listen to a paper by Dr. C. J. Blake, of Boston, on "A New Use of the Membrana Tympani." The paper was illustrated with illuminated photographs by means of Black's stereopticon. A preparation of the ear was shown, in which the membrana tympani had been exposed, and styles attached to the handle of the malleus and the point of the incus. When the membrana tympani was set in vibration by a sound, the style traced a waved line on a bit of smoked glass. The curves formed by different vowel-sounds and by different musical notes were perfectly distinct from each other in character, and each sound had its own particular curve.

Dr. A. Graham Bell, who was present, stated that he hoped this process of phonautography might be of use in the teaching of deaf-mutes. The paper of Dr. Blake was highly interesting.

At 9 o'clock A.M. of Wednesday the Society re-assembled, and, after the reading of records, introduction of delegates, etc., a paper was read by Dr. Ira Russell, of Winchendon, on "State Inebriate Asylums—the Expediency of their Establishment." The writer advocated the affirmative of the question, and ended with the introduction of a resolution that the Society call upon the State to establish inebriate asylums. A lively discussion followed the reading of the paper. Dr. Earle, of Northampton, stated that the law did not permit, nor was it desirable, that inebriates and the insane should be treated in the same institution, and he favored the establishment of inebriate asylums with only such classification of patients as the degree and kind of inebriety under which the patient labored allowed of.

Dr. Tylor, of Boston, said there were recoveries enough from inebriety to call for a rational treatment of this class of patients. He agreed with the previous speaker, that inebriates and the insane should be treated in different institutions.

Dr. Millet, of Bridgewater, differed entirely from the views of the previous speakers. He believed inebriety a crime and not a disease, and he would have cure of the evil attempted by moral influences and legal punishments.

Dr. Godding, of Taunton, in a letter upon the subject under debate, while advocating the treatment of inebriates in separate asylums, strongly urged the necessity of compulsory labor as an essential part of the successful treatment of drunkards in such institutions. The sentences to the asylums must be long if permanent good was to result.

Dr. Woodward, of Worcester, had not much faith in the permanent cure of drunkards. In his opinion, drunkenness was a vice, and not a disease, and the in-

stitutions for its treatment should be penal. As such, they would have little advantage over the existing work-houses and houses of correction. After further discussion by several Fellows, the motion of Dr. Russell was laid on the table.

At 12 o'clock M. the annual discourse was delivered by Dr. George H. Lyman, of Boston, on "The Interests of the Public and the Medical Profession." After having defended the Society against the charge of exclusiveness and intolerance which has so often been made of late, particularly on account of the expulsion of several irregular practitioners from its ranks, he stated that the record of the Society shows that from its origin continuous efforts have been made to raise the standard of preliminary education. A large part of the address was devoted to the consideration of the question as to whether our medical schools and hospitals should be opened to women; if so, whether by the method of separate or mixed instruction; and, finally, whether those able to pass satisfactory examinations shall be admitted to the Society. The orator's opinion was that if women are to be educated as doctors with any prospect of success, it must be effected through the instrumentalities already in operation for the instruction of male students. While not advocating their admission into our medical societies, he admitted a conviction that women should have the higher education they are seeking for, but should find for its development other and more appropriate spheres, which are as yet far from being exhausted.

At 1 o'clock P.M. the Society adjourned to the Music Hall, where between six and seven hundred members enjoyed the festivities of the Anniversary Dinner.

PENN.

BALTIMORE, June 16, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

I WONDER if your readers are aware that Baltimore is indeed a queen among cities, in that she alone of all has a surface-drainage and little or no sewerage. The goddess she worships is Cloacina, and, as is proven by our health officer of the State, E. Lloyd Howard, her very springs are loaded with her offerings of organic matter, obtained from a soil saturated with human excrement from privy-vaults and cul-de-sacs. She is ripe, and her time seems almost full. Some coming epidemic of cholera, yellow fever, or other curse of God will certainly sweep through this great city of 350,000 inhabitants and reap the rich harvest prepared by physical sins. However, a remedy has been proposed in salicylic acid. This disinfectant should be in daily use in our water-tanks, cooking-utensils, privy-vaults, cesspools, garbage-boxes, and in fact in every place where fermentation and putrefaction may exert a baneful influence upon this unsewered and *malo-basinic* city. Oh! that horrid, stinking, dirty, nasty basin; that turbid Jones's Falls; that fruitful source of disease and political pap; that sad ravager of the poor little ones who dwell in the lower strata of this evil purlieu!

"Oh, it is pitiful!
In a whole city full,
Friends they have none."

As a disinfectant, salicylic acid is better than any yet offered, because of its tasteless and odorless properties, its great potency in maintaining liquids in their purity, and its power of arresting decomposition and destroying germ-cells in animal and vegetable life.

Our plan once adopted, Baltimore invalids may again resort to their sulpho-iron springs as has been their wont in days gone by, with their old promise and assurance of health and vigor. It would have interested you, Mr. Editor, to see the many sad long faces next morning at the locked pumps and closed springs here in Baltimore after our learned health officer's discovery, duly noticed by the public prints, that these favorite haunts were saturated with occasional animal débris.

Yours,

OCCASIONAL.

PROCEEDINGS OF SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WEDNESDAY, APRIL 7, 1875.

DIABETES INSIPIDUS, AND ITS TREATMENT BY ERGOT.

DR. DA COSTA related the following case: Stephen S., native of Bavaria, a tailor, was admitted into the men's medical ward of the Pennsylvania Hospital on the 19th of October, 1874. A small, thin man, about 43 years of age, hollow-eyed, with prominent cheek-bones, his complaint of weakness and prostration agreed perfectly with his emaciated appearance. Suffering continually from shortness of breath, from indigestion, with acid eructations, a burning sensation in the epigastrium, complete anorexia, and from immoderate thirst; having his rest at night broken by the frequent necessity for micturition,—he considered but too correctly that his health was lost, and that he was rapidly failing.

No family history could be obtained, and he positively denied any venereal taint. He had always regarded himself as a healthy man until two years ago, when he met with a serious accident. By a fall from the roof of a house he was badly contused, besides sustaining a fracture of his clavicle and some of his ribs, and hurting the back of his head; for nearly a year after this fall he suffered from headache and vertigo.

During the summer of 1874 he had been treated for rheumatism, and was discharged, cured. At this time he was troubled with frequent urinations, and was obliged to rise during the night two or three times. This gradually increased until the date of his re-admission, the day after which (October 20) the urinary examination gave the following result: The urine in color was very light, almost limpid, slightly acid in reaction, the specific gravity only 1.007; it contained neither albumen nor sugar; the quantity in twenty-four hours was 224 fluidounces, corresponding exactly with the amount of water he had drunk.

Conjointly with the troublesome and exhausting flow, the torturing thirst, progressive impairment of hearing, muscæ volitantes principally in the left eye, and shortness of breath, increasing gradually from very slight disturbance to positive dyspnœa, were making his existence a very miserable one.

He was ordered two drachms of infusion of digitalis

and half an ounce of a compound gentian mixture thrice daily, and for the first week improved greatly, the daily amount of urine passed diminishing to 108 ounces. A week later, however, he was passing 252 ounces, and was obliged to retire to his bed, which he had left. The previous prescription was now discontinued, and nitro-muriatic acid, three drops in a drachm of compound tincture of gentian, given him every four hours; he also took ten drops of deodorized tincture of opium four times daily.

He then steadily grew worse, until his condition appeared hopeless. Quinine, stimulants, and animal broths were administered, and the opium and acid mixture were discontinued. He slowly rallied, and was placed on one drachm of the fluid extract of valerian four times daily. The general condition again improved, and on November 17 he passed 195 ounces of urine of the specific gravity of 1.006.

A searching examination was then made of the viscera and nervous system, but the seat of the lesion could not be discovered. The pulse was 84; the respiration varied between 18 and 24. The temperature of the body was 97.5°. It had at no time been higher than 99°, and had repeatedly fallen to 97°, with an evening exacerbation of half a degree, or very occasionally of one degree. A half-ounce of cod-liver oil thrice daily was added to the treatment.

On the 25th he was passing 260 ounces of urine. The valerian was now stopped, as it had so evidently wholly failed, and ten grains of hydrate of chloral were given four times a day; but, as the dyspnœa seemed to increase, this in turn was abandoned in favor of bromide of potassium, twenty grains thrice daily.

During the first days of December the face and ankles became œdematous, the subcutaneous veins of the legs were enlarged, and dark-red lines were visible on the lower extremities, which also pitted readily on pressure. He complained still of a great deal of headache, and of a feeling of tenseness of the skin on the forehead, and furuncles became manifest on the face. His condition was thus little, if at all, changed for the better.

It was then determined to give him ergot, which was at first resorted to hypodermically; but this caused so much local disturbance that the remedy had to be administered by the mouth.

The internal use was begun on the 7th of December, one drachm of the fluid extract being given three times daily; this was increased on the 18th of December to two drachms thrice daily. The diet was the same as before; the cod-liver oil was continued for a time, but not with great regularity, and it was presently wholly stopped.

From the time that the treatment by ergot was instituted, there was steady diminution in the daily amount of the urine, and rapid improvement in the patient's health; indeed, this was without a drawback, with the exception of a slight attack of pleurisy followed by some congestion at the base of the lung, and lasting only a few days. The patient was practically well on the 25th of January, 1875, when the ergot was discontinued; but he was retained under observation until March 10, in order to decide whether the improvement was a permanent one.

When discharged, he was well and strong, and he had never been in better health. During his stay with us he gained in weight forty pounds; and it was difficult to recognize, in the fat, bright-eyed, jovial man who left the hospital, the lean, languid-looking, dejected patient who had come to it but a few months before apparently to die.

From the first of the year to the date of discharge, the maximum amount of urine passed was seventy-four ounces, and it had been several times as low as forty ounces per day.

The history of this case, as of many others, shows the source of the disease to be the same indubitable nervous disorder. But whether it be, as seems most probable, in the sympathetic nervous system, or the derangement leading to loss of control be simply reflected to this from the cerebro-spinal, is a matter, with our present knowledge, of the merest conjecture. In a number of the autopsies made—they are not, it must be stated, very numerous—the lesion has been located at the base of the brain, or in the cerebellum or the medulla; but there are records of the disease in which injury of the abdominal ganglia by a tumor gave rise to the distressing malady.

Diabetes insipidus is, when well marked, for the most part a fatal disorder, though the patient may be kept in fair health for years.

This case is the first one which Dr. Da Costa has seen recover in which there were such grave symptoms besides the excessive flow of urine. That the recovery was due to the ergot there can be no doubt, and its effect on the capillaries, both of the nervous centres and the glandular organs, suggests its mode of action.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

MAY 3, 1875.

IN the absence of the Director and Vice-Director, Dr. J. H. MCQUILLEN was called to the chair.

The Report of the Committee on Dr. Seiler's paper upon the "Photographic Enlargement of Microscopic Objects," recommending it for publication in the *Philadelphia Medical Times*, was read, accepted, and the committee discharged.

A paper on the "Physiological Action of Hemlock and its Alkaloids," presented by Prof. H. C. Wood, Jr., for B. F. Lautenbach, M.D., was read by title, and referred to a committee composed of Drs. Schaeffer, Richardson, and Reed.

Verbal communications being next in order, Dr. J. GIBBONS HUNT made the following remarks:

"Mr. Director,—Anticipating more than the usual amount of intellectual and microscopical dry weather at the Section this evening, I have brought with me a few slides for the inspection of members, believing they show some interesting points of histological detail with considerable distinctness.

"I am unfortunate in having no very distinguished microscopical friend residing at a distance to kindly send me preparations for exhibition, but am compelled to rely upon domestic manufacture, which, of course, cannot claim to rank with those of foreign make.

"Still, when properly illuminated, as these now are, the members may see the intestinal villi of the rabbit perfectly injected, and mounted in natural position, so that the mucous surface appears with the entire columnar epithelium attached, each cell distinct. Most of the villi show the muscles of Brücke clearly. In the muscular coat of the same intestine the lymphatic vessels appear without injection.

"A slide containing a piece of mesentery of juvenile cat shows one dozen Pacinian bodies, which must be seen under the binocular to be properly appreciated. These supposed nerve-terminations in dead cats vary greatly in size and apparent complexity of structure, being from the $\frac{1}{100}$ th of an inch up to a magnitude which unaided vision can detect. The fat-tissue is well injected, and the crystallized fat appears *in situ*, not having been dissolved out as is usually the case. The nerves are preserved with less structural change than I have seen elsewhere. Their nucleated filaments appear

winding around the vessels and distributed to their coats with great distinctness. The elastic connective-tissue fibres are all apparent, and their mode of inosculation may be studied.

"An injected solitary gland of the large intestine of the rabbit shows it to be structurally like the individual gland in Peyer's patches. In the same specimen we can look right down into the open orifices of innumerable follicles of Lieberkuhn, which display all the epithelium *in situ*.

"A slide of the cæcum of the rabbit shows that organ to be simply an aggregation of glands resembling those in Peyer's patches, having, of course, between them villous prolongations unlike mucous surfaces elsewhere.

"I am conscious that such plain and easily demonstrated histological details are neither rare nor difficult; but, knowing they would be new, and possibly interesting to the members, I venture to offer them for examination."

After a recess of ten minutes, allowed for the examination of these interesting specimens, the chairman inquired of Dr. Hunt what menstruum he had found most useful for the preservation of nerve-tissue.

Dr. HUNT replied that, since we have never seen a fresh and living nerve-cell or fibre, we possess really no standard for judging of the success of any method of preparation; but that in his experience nerve-structures underwent the least possible change if immersed in a weak solution of glycerin in camphor-water, whose strength was gradually increased by the addition of more glycerin until a suitable preservative fluid was obtained.

Dr. J. G. RICHARDSON inquired of Dr. Hunt whether he had not distinctly seen in the tails of living salamanders living nerve-fibres which would serve as standards of comparison.

Dr. HUNT replied that such nerve-fibres could be seen as distinctly as the layers of connective tissue and epithelial cells would permit.

Dr. RICHARDSON added that since red blood-corpuscles circulating in vessels at the same depth, and hence observed through the same intervening layers of connective tissue and epithelium, exhibited appearances identical with those of other red corpuscles from the individual salamander immediately after their exit through a wound of the integument, he believed he might fairly conclude that the nerve-filaments thus seen *were distinctly visible*, and that therefore the somewhat irregularly swollen and knotted outline they presented was a normal character of healthy living nerve-fibres, and not a pathological or post-mortem change.

Dr. CARL SEILER announced for the benefit of members that there was now in operation at the University of Pennsylvania in West Philadelphia, under the care of himself and other gentlemen, a physiological laboratory, affording room, apparatus, and, to a certain extent, material, for original investigations, which any physician might carry on at a small expense. The laboratory (which was connected with a microscopical department) was open from 10 A.M. to 5 P.M., and was, he believed, the first of its kind in this city, or perhaps in this country; although similar institutions had long been established in Heidelberg, Vienna, and other Continental seats of medical science.

THE MONASTERY OF ALTENBERG have advertised for a resident physician, who is to receive, besides his board and lodging, a salary of about \$100 per annum. For this munificent salary he is not only to give his professional services to the sick in the monastery, but will be expected to take charge of the hair and beards of the holy brethren.—*N. Y. Medical Record*.

REVIEWS AND BOOK NOTICES.

PNEUMOTHORAX. By AUSTIN FLINT, SEN., M.D., Professor of the Principles and Practice of Medicine in Bellevue Hospital Medical College; being No. III. of Vol. I. of a series of American Clinical Lectures. Edited by E. SEGUIN, M.D. New York, G. P. Putnam's Sons, 1875.

In this brochure from the pen of one of our foremost clinical teachers we find of course an excellent exposition of our present knowledge of pneumothorax in its medical aspects, illustrated by several typical cases of the disease. The author considers the accident of air entering the pleura as dependent upon the following four conditions, viz., "First, empyema; second, interstitial emphysema; third, circumscribed gangrene of the lung; and, fourth, phthisis." In the latter connection he inculcates the wise caution (so timely in these days of almost universal aspiration for fame) against wounding the pleura with Dieulafoy's needle. Prof. Flint also proposes to cure some rarely favorable cases of pneumothorax complicating consumption, "when the amount of phthisis is small, the disease non-progressive, and all the circumstances favorable for arrest and recovery, aside from the perforation of the lung," by free incision in the chest-wall; an original suggestion which seems worthy of more extended trial, in spite of the failure in two instances which its author so honestly records.

J. G. R.

GLEANINGS FROM OUR EXCHANGES.

CEREBRAL RHEUMATISM.—Among the complications which threaten rheumatism, none are more formidable than those which attack the brain, and which for want of a better name are designated cerebral rheumatism. They are not always of the same form or gravity, and their cure sometimes supervenes without any active treatment. Sometimes chronic delirium results, and forms the beginning of a variety of mental alienation now well known. The favorable cases are not the most frequent. Among the phenomena observable in cases which terminate fatally, there are two which are of great value in prognosis, viz., extreme elevation of temperature, and sudden and complete disappearance of pain. When delirium occurs in such circumstances, death is not far off. Coma succeeds the delirium, and death follows in a few hours. Dr. Blachez reports at much length a case in which, following the example of his colleague, Dr. Raynaud, he had the patient placed in a cold bath at a temperature of 73°.4 Fahr. (23° C.), which was gradually lowered, by addition of ice, to 68°, and kept therein an hour and a half. The result not having been discouraging, the bath was repeated ten times at temperatures varying from 61° F. to 77° F. (16° to 25° C.) within four days, after which the patient regained consciousness, and subsequently recovered health. The lower temperature had to be abandoned, as its immediate effects were alarming—*Gazette Hebdomadaire**; *Irish Hospital Gazette*.

HATHORN SPRING WATER.—The *Boston Medical and Surgical Journal*, June 10, contains a communication by Dr. S. A. Fisk, of Northampton, on the waters of the recently discovered but famous Hathorn Spring of Saratoga.

These waters belong to the class known as alkaline-saline; the large amount of carbonic acid gas contained not only increases the solvent powers of that menstruum, enabling it to take up and hold in solution

a favorable combination of ingredients, but renders them very easy of digestion, and to most persons very agreeable to the taste. In taste and general character the Hathorn resembles the celebrated Congress Spring water; it is stronger, however, in some of its constituents, more prompt and certain in its action, and contains also a bicarbonate of lithia, which renders its diuretic properties of great value.

From personal experience Dr. Fisk speaks very favorably of Hathorn water. Its therapeutic action is very prompt. When taken in the morning it is agreeable to the taste, grateful to the stomach, and acts efficiently as an evacuant; and while it may, and in many cases does, induce full and copious dejections, they are not attended with pain; neither is languor or debility experienced by the patient; but, on the contrary, a feeling of refreshment and invigoration. The powers of assimilation and nutrition are increased, the appetite being favorably affected at once. That sense of fullness formerly termed "abdominal plethora," where the liver, spleen, and mesentery are more or less engorged with blood, and where hemorrhoids are present, is diminished, with a gratifying sense of relief.

When taken more frequently and in smaller quantities than the cathartic dose, its effect upon the kidneys is no less happy. Its action is prompt, uniform, and quite certain. A turbid, irritating urine is quickly cleared up by it; the ureters and bladder are soothed, and many cases of vesical catarrh are quite relieved by it. In some of the cutaneous diseases, those more especially dependent upon an acid state of the secretions, these mineral waters are beneficial both from their alkaline properties and from their depurative effects.

The following is the analysis of the Hathorn Spring:

Chloride of sodium	509.968 grains.
Chloride of potassium	9.597 "
Bromide of sodium	1.534 "
Iodide of sodium198 "
Fluoride of calcium	a trace.
Bicarbonate of lithia	11.447 "
Bicarbonate of soda	4.288 "
Bicarbonate of magnesia	176.463 "
Bicarbonate of lime	170.646 "
Bicarbonate of strontia	a trace.
Bicarbonate of baryta	1.737 "
Bicarbonate of iron	1.128 "
Phosphate of soda006 "
Biborate of soda	a trace.
Alumina131 "
Silica	1.260 "
Organic matter	a trace.

Total solid contents 888.403 "

Carbonic acid gas in 1 gallon, 375.747 inches. Density, 1.009.

HEMIPLEGIA WITH CLOT UPON THE SAME SIDE OF THE BRAIN.—At the recent meeting of the American Neurological Association, Dr. Hay, of Chicago, presented an interesting specimen of this kind, removed from a female patient *æt.* 55 years, in whom there was hemiplegia of the left side, face not involved, and the tongue could be protruded without deflection. The patient jumped from a railroad-train which was moving at a rapid rate, and was picked up insensible, in which condition she remained for about three weeks. She suffered from incontinence of urine and *fæces*. At post-mortem a meningeal clot was found over the frontal convolution, upon the left side of the brain, about a line in thickness, three-fourths of an inch in length, and about the same in width. No morbid conditions were found in any other part of the brain, and the clot was limited to this region.

* Cf. an admirable article on this subject by Dr. Da Costa, in the *American Journal of the Medical Sciences*, January, 1875.—Ed. I. H. G.

GASTROTOMY (*The Lancet*, May 15, 1875).—Mr. Sydney Jones reports the following case. A man, æt. 67, had had difficulty of swallowing for ten months, and for seven months had been unable to swallow solids. He had lost his voice for four months, although there was no difficulty of breathing. A bougie did not pass beyond the commencement of the œsophagus; and on bending the head forward, so as to relax the front cervical muscles, a hard tumor could be felt on the left of the trachea, behind the sternal end of the clavicle, too low down to promise anything from attempt at œsophagotomy. He had lost very much flesh. Previously stout, his abdomen was now fallen away, the ensiform cartilage projecting as a hook-like process. He complained much of hunger, and of persistent sinking pain at the pit of the stomach. His difficulty of swallowing liquids was increasing; and a constant discharge of mucus from his pharynx caused him much trouble. He did not complain of pain in the neck-tumor, which was discovered only after exploration for the cause of the stricture. It was impossible to do œsophagotomy, and it was decided to perform gastrotomy. It had been ascertained by previous experiment that the readiest mode to secure the stomach, and in the best position, was to incise along a line drawn from the outer border of the left nipple to the outer border of the spine of the pubis on the same side. An incision was made along this line for about three inches and a half, beginning about an inch below the costal cartilages. The outer border of the rectus muscle was easily hit; no muscular fibres were divided; only a little venous hemorrhage occurred; and the stomach was easily caught, and at once drawn through the opening by the finger and thumb passed into the peritoneal cavity. The stomach was brought into connection with the side of the wound by sutures, the rectus muscle being included in the sutures, and the edges of incision above and below brought together by needles.

He was then fed for five days by enemata, and afterwards by the stomach. Forty days later he died from bronchitis. At the post-mortem examination firm and complete union was found between the stomach and the abdominal wall.

SUPPURATING HYDATID CYSTS IN THE THIGH—DEATH.—The following case was under treatment lately at St. Thomas's Hospital. The patient was a strong, healthy-looking man of 45. About two years previously he had hurt himself in the left femoral region, and soon after noticed a tumor in this locality, which grew at first slowly, later rapidly, and caused swelling of the foot and leg.

On examination, a distinctly fluctuating tumor, about the size of a foetal head, was found situated in the left Scarpa's triangle. The size of the swelling remained unaltered whether the patient was standing or recumbent. There was no impulse on coughing. He could bear his weight on the affected limb. There was no tenderness in the spinal region, and pressure in the iliac fossa caused no discomfort. There was no aneurismal pulsation or bruit, moderate manipulation gave little pain, but rough handling caused much suffering. After the patient's admission the tumor became more and more inflamed, and was finally evacuated, yielding four pints of purulent fluid, loaded with hydatid cysts. A few days later the patient succumbed.

Post-mortem examination showed nothing unusual outside of the tumor.—*Lancet*, June 5.

THE SWEAT-GLANDS (*Boston Medical and Surgical Journal*, June 3, 1875).—Dr. Aubert has published an article based upon observations made by studying the impressions obtained by the application of the hand to sheets of paper impregnated with nitrate of silver, protonitrate of mercury, and various other substances.

These impressions were of two kinds: dotted ones, produced by the hands after being carefully washed, in which each point corresponds to a sweat-gland; and linear ones, produced by the unwashed hand, the lines corresponding to the ridges of the papillæ. By this new method of exploration Dr. Aubert comes to the following conclusions:

The insensible transpiration is performed exclusively by the sweat-glands.

The moisture is due not only to the constant discharge of the perspiration, but also to the presence of the deliquescent alkaline residue left by its evaporation.

The sweat-glands, independently of their other functions, should be regarded as a secretory apparatus attached to the organs of touch.

This last view is of significance in connection with certain facts to which he calls attention: the inequality of the number of sweat-glands in different localities, and their predominance in the palm of the hand and the sole of the foot; the inequality in their activity also in various parts; the persistence of secretion, and of its escape upon the hand and foot in spite of pressure; the relation of proximity of the sweat-glands to the papillæ; finally, the acidity of the sweat at the moment of its secretion, and the alkalinity of its residue.

AN EASY AND EFFECTUAL METHOD OF ARTIFICIAL RESPIRATION IN INFANTS.—Dr. J. B. Mattison presents the following modification of Dr. Byrd's method: The infant upon its back, firmly grasp the outer thigh, the index-finger and thumb encircling, and the inner limb resting on the fore-arm, while the little finger is extended as far as possible up the back to form a fulcrum with the corresponding finger of the opposite hand. In the hollow formed by the thumb and forefinger of the right hand allow the neck of the infant to rest, with the palm under the shoulders and the little finger extending down the back to meet its fellow of the other hand. Now, gently and regularly depress the vertex and inferior extremities as much as practicable below the horizontal, say forty-five degrees, thus facilitating inspiration, and, after a proper interval, elevate them to the same extent, forming a concavity of the chest and thereby forming expiration. Continue these movements without interruption, taking care to permit no impediment to the exit and entrance of air during the upward and downward movements of the head and chest, and also exercising caution against too much lateral motion of the head during their continuance. The conjoined use of Désormeaux's douche, or a little cold water dashed occasionally on the epigastrium, will tend to enhance the efficacy of this method; indeed, its employment does not at all preclude the use of whatever auxiliary measures may be deemed advisable.—*New York Medical Record*.

KOROWIN ON STARCHY FOOD FOR INFANTS.—In the *Jahrbuch für Kinderheilkunde und Physische Erziehung* Dr. Korowin states that a secretion may be obtained from the mouth of a child as soon as it is born, though in minute quantity and with difficulty.

It is generally found to be acid, unless the mouth of the child has been previously washed carefully, when it has a neutral or alkaline reaction. The effect in converting starch into sugar of the secretion of the salivary glands of the mouth and that of the pancreas was obtained by making infusions from the glandular tissue and observing the changes produced upon solution of starch. It was ascertained that till the end of the third week the glandular secretion of the mouth exerts no influence of this kind, though the pancreas does, and always to a much greater degree than the former.—*London Medical Record*.

SATURDAY, JULY 10, 1875.

ORIGINAL COMMUNICATIONS.

ON THE TREATMENT OF BRIGHT'S DISEASES OF THE KIDNEY.

BY JAMES TYSON, M.D.,

Prof. of Pathological Anatomy and Histology in the University of Pennsylvania.

Read before the Philadelphia County Medical Society, March 10, 1875.

ALTHOUGH the line of demarcation in the treatment of the different forms of Bright's disease is by no means so sharp as that which modern histology has made in their pathology, it will, nevertheless, facilitate our consideration of the subject, as well as perhaps tend to place treatment on a more rational basis, if I preface a brief recapitulation of the different forms alluded to.

1. In the first place, we have the division into *acute* and *chronic* Bright's disease. The former presents us with a single form, that of *acute nephritis*, the acute tubal nephritis, acute catarrhal and acute desquamative nephritis of certain authors,—which has its most frequent occurrence as a sequel of scarlet fever, and therefore in children; while it also occurs less commonly in adults after exposure, especially while perspiring, to cold and moisture. It is indicated by the presence of dropsy, bloody highly albuminous urine, containing blood-casts and epithelial casts, also sometimes hyaline fibrinous casts.

2. Secondly, we have chronic Bright's disease, which gives us four subdivisions. The first of these is the *large white kidney*, also called chronic catarrhal nephritis, and chronic tubal nephritis, because it involves more particularly the cells lining the uriniferous tubules, and is generally found in continuation of the acute nephritis. The condition, while one of increased nutrition, a true hypertrophy in its earlier stages, and a fatty degeneration in its later contracting stage, cannot be considered an inflammatory one; and therefore I prefer the term *large white kidney* to any involving the idea of inflammation.

In this form of disease we have also dropsy, considerable albumen, at first small hyaline casts, containing an occasional oil-globule or fragment of epithelium, later more copious urine and more numerous small hyaline and oily casts, and finally large hyaline, granular, and oil casts, indicating destruction of the gland, the rate of which may be estimated by the quantity of this kind of deposit.

Next we have the *cirrhotic* or chronically contracted kidney, also called the gouty kidney, and by the German pathologists the kidney of interstitial nephritis, in contradistinction to the catarrhal nephritis, because the interstitial connective tissue is believed to be the seat of the inflammation. Here again I do not think the phenomena are those of a true inflammation, but rather of a nutritive activity in the normally scanty connective-tissue elements between the tubules, to the resulting

fibrillar element of which is also contributed a portion derived from the atrophy of the tubules themselves. A hypertrophy of the muscular coats of the arterioles of the kidney, and perhaps, also, as claimed by Johnson, of the entire arterial system, is also an essential feature.

For the above reasons I prefer, also, to speak of this kidney as cirrhotic or contracted, its small size and hardness being more conspicuous than inflammatory phenomena. In this form there is little or no dropsy; there is an increased amount of urine, with a minute amount of albumen, sometimes, perhaps, not a trace of it; also granular and hyaline casts.

Third, is the *albuminoid* kidney, also called the bacony (*speckige*), waxy, or amyloid kidney, the latter term having been applied by Virchow in consequence of an erroneous conception of the nature of the infiltrating substance, he having supposed it to be allied to the starches.

The essence of the disease consists in an infiltration, first of the walls of the blood-vessels, and finally of the tubules and cells themselves, with this peculiar substance, of which the exact composition is still unknown, but which is certainly albuminoid and not starchy in composition. The effect of the infiltration is to give a peculiar glistening translucency to the parts affected, and to impart to them the property of striking a bright mahogany-red color with a solution of iodine.

The disease is commonly found attending an exhausting drain upon the system, whether from local or constitutional disease, and it is highly probable that one of these causes is the extreme albuminuria which attends the large white kidney, so that we find the latter organ often the seat of a secondary albuminoid disease of the capillary blood-vessels. Except under these latter circumstances, albuminoid disease of the kidney is generally accompanied by similar disease of the liver and spleen, which are also enlarged, and by this condition aid in the diagnosis. In this affection the amount of urine is large and correspondingly pale; the amount of albumen, at first small, gradually increases; casts are often absent, and when present are not numerous, and they are usually small, hyaline, and granular, and occasionally oily. Later, we have the same large-sized hyaline and granular casts described as occurring in the large white kidney; and from the latter form of disease it is often impossible to distinguish the waxy kidney before death. Sometimes the casts in albuminoid disease exhibit the waxy lustre of the albuminoid infiltration, and strike also the red mahogany-color with iodine.* But this is by no means invariable, or we would have a means of easy diagnosis.

Finally, there undoubtedly sometimes occurs a pure and simple fatty degeneration of the cells of the kidney, often associated with general fatty infiltration of all the tissues, and especially of the liver and heart, in very fat persons, consumers of

* Care should be exercised to use a watery solution of iodine in testing these casts under the microscope, as an alcoholic solution precipitates the albumen and obscures the field.

alcohol, or the subjects of wasting diseases like cancer and phthisis.

TREATMENT.

It is to be regretted that the advance in the therapeutics of Bright's disease has not been as great as in its pathology; and yet, that treatment is often of the greatest utility, not only in alleviating the suffering and prolonging the life of the patient, but also in promoting recovery, is attested by numerous instances. As already stated, the treatment of the different forms of the disease is by no means so distinctive as their pathology, and, for practical purposes, a division of the treatment into that for the acute and that for the chronic is sufficient, provided that attention be also called to any special modification of treatment required by special conditions.

Treatment of acute Bright's disease.—First, as to the treatment of the acute form. There is no doubt that many cases recover while the conditions of rest, quietude, and warmth are maintained. And it is further certain that, whatever other means of treatment are used, these three conditions are absolutely necessary to recovery. A patient with acute Bright's disease, therefore, whatever its mode of origin, should be put to bed, kept quiet, and warmly covered. I should seldom, however, be satisfied with this mode of treatment alone. The selection of other remedies will depend somewhat upon the severity of the case. If the urine be suppressed, dry cups, or even wet cups, to the loins will so divert the blood as to permit a relief to the stagnation which always exists in the acutely inflamed kidney. These cups should always be followed by a warm, moist poultice to the same region, which, indeed, should be used under any circumstances, whether the cupping is necessary or not. I am in the habit, therefore, of always resorting to poultices, and, if the symptoms are at all severe,—that is, where there is complete or almost total suppression of urine, nausea, headache, or delirium,—of preceding them by cupping. Although at first thought it would seem that the kidneys are quite remote from the seat whence the blood is immediately removed, it must be remembered that we are relieving the blood-pressure in the lumbar arteries which come off from the aorta near the renal arteries, and thus divert the blood from the latter. Under all ordinary circumstances dry-cupping is sufficient; wet-cupping should be reserved for the most extreme symptoms, where the strength of the patient has not been previously reduced. Some care must, however, be exercised in the use of dry-cupping, lest we defeat its end. The object of dry-cupping, as justly observed by Dr. G. Johnson, is to facilitate the movement of the blood through the capillaries into the veins,—to draw the blood rapidly through the part, and thus relieve the pressure of the blood in the renals. To do this, the cups must be removed as soon as there is a decided redness, and placed on another part in the vicinity. By allowing them to remain too long, the blood is stagnated in the capillaries, its onward movement prevented, and there is, therefore, no derivation of blood from the involved organ.

The above means have for their object the direct

relief of the congestion of the kidney. This is not the only indication while the kidney is congested. The congestion, in some instances, is altogether due to an excess of work thrown upon it in consequence of suppressed or deficient action of the skin, and in all cases the carrying out of the natural function of the organ tends to increase any existing congestion. Can the kidney be in any way relieved of this functional irritation? Is there any organ which, in other words, can supplement the kidney? Such an organ is the skin. A second indication, therefore, is to excite the action of the skin. And in fulfilling this lies the advantage already referred to from the maintenance of warmth and avoidance of cold early insisted upon. But we are not confined to these protecting measures. The skin may be made to do the work of the kidney itself, and thus one of the most alarming dangers of Bright's disease, uræmic intoxication, averted, while at the same time the congestion of the kidney is also relieved.

The class of remedies which produce this action are diaphoretics; and, of the internal remedies, none is better than the ordinary sweet spirit of nitre, especially if it be combined with small doses of ipecacuanha. But a more effectual and certain method of accomplishing the same end is by warm baths, or, better still, by the so-called warm or "cold pack," in which the patient is wrapped in a wet sheet and then enveloped in a sufficient number of blankets. Perspiration is thus copiously induced, and when thus caused is agreeable, and never attended by the faintness which sometimes follows the use of the hot-air bath,—another means of accomplishing the same end, which will be further considered under the treatment of chronic Bright's disease. In an ordinary severe case of acute Bright's disease, a single pack of this kind will remove all symptoms which may cause anxiety, and happily inaugurate the convalescence, while it may be repeated daily, if necessary.

We may resort to purgatives to the same double end, that of relief of congestion and a complementary action of secretion, and to a certain extent these should always be employed. But the reason for which I primarily employ a purgative is less for either of these objects than for one which I deem even more essential, and that is to promote the action of other remedies, a purpose which applies not only to the treatment of Bright's disease, but also to all diseases. It is a well-known fact in the absorption of fluids, which is borne out by the phenomena of osmosis, that this does not take place rapidly when the blood-vessels are congested and there is a slowly-moving current.

The beautiful experiment of Magendie, which consisted in injecting into the peritoneal cavity a colored fluid, which at first was not appreciably absorbed, but which, on opening a blood-vessel, disappeared rapidly before his eyes, is sufficiently to the point in illustration. The treatment of any case of acute Bright's disease is therefore well commenced by the use of a cathartic, and after its effect the prompt action of other remedies may be looked for. Indeed, it is quite useless to administer diu-

retic remedies before some action is obtained from the bowels, as they will be many hours in producing their effects; whereas after such influence they will be as many minutes. Beyond this end I am not in the habit of giving purgatives in ordinary cases of acute Bright's disease. But there is a condition in which the eliminative action already referred to is often of signal service, and that is the one of uræmic coma and convulsions. Under these circumstances, when the patient cannot be made to swallow, and decided and prompt effect is desired, a couple of drops of croton oil on the tongue have many times saved life by inducing prompt and decided purgation.

Nothing has been yet said of the use of diuretics, which are, perhaps, the first means thought of by most practitioners in the treatment of Bright's disease, acute or chronic, and, no doubt, in many cases they deserve an early consideration. Yet the propriety of their use has been much disputed, and at first thought there would seem to be legitimate objection to them in the treatment of acute nephritis, for with the idea of increased secretion of urine is generally associated that of an increased flow of blood to the kidney. And the question naturally arises, Shall a kidney already congested and inflamed be further jeopardized by crowding more blood into it? On the other hand, it is well known that convalescence in a case of acute Bright's disease which has been left to recover without treatment is always ushered in by a most copious diuresis. This is usually explained by the fact that urea itself is a decided diuretic, as may be shown by injecting it into the blood-vessels of any animal,—an operation which is followed by copious diuresis. In the early stages of Bright's disease the urea and other organic constituents are retained in the blood, and when the circulation through the kidney becomes free, they exert their diuretic action. It will be observed, however, that this takes place only after the circulation becomes free, and it must be looked upon, therefore, not so much as a cause as a result of an improvement in the condition of the organ. Nevertheless, to facilitate such a condition of affairs as copious secretion of urine, and with it the elimination of those effete matters the accumulation of which constitutes the chief danger of Bright's disease,—uræmia,—can only be considered desirable if it can be done without exciting congestion of the kidney. The secret in the proper use of diuretics lies in the selection of such as effect their object without producing a congestion; and such there are. To understand this properly, it must be recalled that the secretion of urine is largely a process of filtration, a process of squeezing out the water and dissolved elements by pressure from behind, and that this is accomplished in the Malpighian bodies by the agency of the arterial pressure and the force of contraction of the heart. It must be remembered that there are two sides to the renal capillary circulation, an *arterial* side and a *venous* side. The first consists in the afferent arteriole and the capillary ball contained in the dilated end of the convoluted tubule and forming with the latter the Malpighian body; the second,

of the capillary net-work formed by the splitting up of the efferent vessel after it leaves the Malpighian capsule and closely embraces the convoluted tubules. The area of this is great, and the movement of the blood slow. As a consequence, a condition favorable to increasing the blood-pressure in the Malpighian body exists. Such pressure is obtained by increasing the force of the heart's contraction, or increasing the arterial pressure by the introduction of fluids within the blood-vessels. The effect of this is to produce a more rapid filtration; that is, more water is squeezed out from the blood-vessels into the Malpighian capsules, whence it is carried downward in the tubules. Now, whatever remedies increase the force of the heart's action or the arterial pressure by absorption of fluids will increase the amount of water thus filtered out. Such remedies are digitalis, the salines, and diluent drinks generally,—digitalis by increasing the force of the heart's action, the salines and diluents by increasing blood-pressure through their absorption. Digitalis is certainly the diuretic most to be relied upon, and when combined with the salines, freely diluted, affords a powerful lever for good. It is necessary, however, to have a reliable preparation, and unless one is sure of the quality of the tincture it is best to use a freshly-prepared infusion. At the same time it is also true that much smaller doses of the tincture are usually given than of the infusion. Thus, of the latter, fss is often administered, equivalent to three and three-quarter grains, while eight minims or sixteen drops of the tincture, equivalent to one grain of the powder, are considered a full dose, a discrepancy which must account for at least a portion of the diminished effect of the tincture. Digitalis should therefore be given in sufficient quantity,— fji of the infusion to children, and fss to adults,—repeated every three hours until an appreciable effect is produced on the rate of the pulse, when it should be diminished. Not until then can you look for a diuretic action. Digitalis, when thus administered, should, of course, be watched, and the patient should be seen twice a day until an effect is produced. Of the alkalies with which it may be combined, acetate of potassium and citrate of potassium are to be preferred. Their diuretic action doubtless depends upon the impetus they give to the osmosis of fluids which hold them in solution, thus increasing the arterial tension and contributing to the flushing of the kidney. Half a drachm of the potash should be given every two or three hours to adults, and ten grains to children. There can be no doubt that an increased filtration of water into the Malpighian capsules aids the separation of the organic constituents in the second capillary net-work referred to, both by facilitating osmosis on the principle of the more rapid current, and by washing out of the secreting cells of the convoluted tubules the organic matter already excreted by them.

By such means as these, after the unloading of the blood-vessels by the action of a purge, we may greatly serve our patient through diuretics. On the other hand, turpentine, cantharides, copaiba, and the class of diuretics which produce a congestion and stagnation of blood in the second or venous

capillary net-work, are mischievous, and should not be employed.

It should not be omitted to mention that fomentations of a strong infusion of digitalis (3i to a pint) applied to the abdomen or lumbar region are often efficient in producing diuresis when other means fail.

Treatment of chronic Bright's disease.—There is always an intermediate stage between that of acute nephritis and the condition of the large white kidney from which recovery often takes place, which calls for a modification of or an addition to the treatment described for the acute, and which is indicated by an impaired quality of the blood, due partly to the gradual accumulation of effete matter, and partly to the drain upon the system which a copious albuminuria certainly induces. But, as it is a condition growing out of the prolonged presence of the disease, it is practically covered in the treatment of the chronic form, and requires therefore not to be separated from it.

The chief indications in the treatment of the chronic forms of Bright's disease are two: *first*, to improve the quality of the blood, which has become anæmic and loaded with urea and allied organic compounds; and, *second*, to combat the symptoms and complications which form a source of great inconvenience, and even danger, to the patient.

The first of these indications is chiefly fulfilled by the use of iron, quinia, and strychnia, nourishing food, and proper hygienic influences; and also by depurating the blood of its retained urea. The well-known Basham's mixture, really a solution of acetate of iron, made by adding to tincture of the chloride acetic acid and the solution of the acetate of ammonia, has the advantage of at least tending to eliminate, while it also restores. But the tincture of the chloride alone is a powerful agent which is always accessible, and, when combined with the sweet spirit of nitre, is perhaps as efficient as the Basham's mixture. To either, the quinia and strychnia may be added if desired; while to the latter the infusion or tincture of quassia makes a compatible addition.

With regard to *food*, while it is true that an abundance, and of good quality, is desired, a question has properly arisen as to the propriety of using the highly nitrogenized substances, as animal flesh. It is now well determined that the urea formed in the blood and eliminated in the kidneys is derived chiefly from the azotized elements of the food, and that the more nitrogenous food we consume the more work is thrown upon the kidneys; although here too the question is somewhat different if we suppose the separation of the urea a matter of mere filtration, or one of elaboration. But either supposition involves an increased flow of blood to the organ; and, although I cannot speak from any certain knowledge that disadvantage results from the free use of nitrogenous food, I feel that the probabilities from theoretical reasoning are sufficiently strong to make it proper for us to be influenced in practice by them. While, therefore, it is not desirable to omit all such food, it is desirable to limit it to moderation, and, while drawing elements of mixed food from the

vegetable kingdom, to make up the deficiency in meats by the free use of milk. There is reason to believe the milk-treatment of cases of Bright's disease to have been of signal advantage in certain instances, and it is not unlikely that it depends upon the smaller proportion of nitrogen contained in it, compared with a corresponding quantity of meat.

Under hygienic measures are included a proper use of clothing and exercise. That the former next to the body should be of *wool* is absolutely essential. For it must be remembered that, on the one hand, the skin is a powerful adjuvant to the kidney in its eliminating operations, and, on the other hand, that any interference with or suppression of the action of the skin must throw more labor on the kidney. Cold is the agent which produces such suppression, and warmth the means by which the action of the skin is encouraged; and no texture prevents the former or secures the latter more effectually than wool.

For the same reason, while the maximum amount of fresh air is desirable, cold and dampness should be avoided or sufficiently guarded against. Many a case of chronic Bright's disease, often previously undiscovered, has been brought to its fatal termination by the action of cold, and especially of cold and moisture combined. Hence, too, there is no doubt that residence in a warm and equable climate is often of signal service in cases of chronic Bright's disease; and cases are reported where albumen has disappeared and recovery apparently taken place in a warm climate, where their previous duration was such as to make recovery highly improbable.

It is doubtful whether other measures than the above are necessary in cases of *contracted kidney*, where the external symptoms of the disease are often so trifling that they have never been observed by the patient; while the discovery of the presence of the disease is often accidental, as where the patient consults his physician for an inexplicable weakness, and the latter in exploring the case discovers albuminuria and casts. In these cases the complication of dropsy seldom occurs; and the extent to which life may be prolonged by suitable care may only be limited by its natural termination. On the other hand, such a person, with the disease undiscovered and uncared for, is in hourly danger from the uræmic intoxication which a shower of rain or a period of unusually prolonged mental and bodily fatigue may cause.

It is more particularly in the *large white kidney*, and the later stages of the *albuminoid organ*, that more decided measures are called for to depurate the blood of its accumulated impurities, as well as to combat the symptoms which cause inconvenience or jeopardize life. These symptoms are those of dropsy, effusions into the serous cavities, and congestions. Such patients are usually confined to the house, or go out of it at such great inconvenience as to make it intolerable to do so. Of dropsy there is abundant evidence to the naked eye; but of the necessity of depuration there is unfortunately no direct means of estimation except by a volumetric analysis of urine, which involves so much trouble and care as scarcely to be possible to the general

practitioner. Fortunately, however, the means which are best calculated to relieve the one are most likely to relieve the other. These measures are, in addition to diuretics, such as promote a more decided action of the skin than any yet alluded to, and certain purgatives.

With regard to diuretics, nothing need be added to what has been already said, bearing in mind that digitalis is our most powerful lever. But with regard to measures which promote a decided action of the skin, I desire to add a little more. These are the "warm pack-bath," and the hot-air bath already alluded to. The latter, in consequence of its more ready application, is to be preferred whenever it can be borne. I have recently, in my wards at the Philadelphia Hospital, used considerably the hot-air bath, and made some observations to determine its value; the results of which satisfied me that we have a much more useful agent than many of us have suspected. A patient with large white kidney was under my observation for more than a year. During a portion of this time his urine was carefully measured, and a portion of the twenty-four-hours' urine analyzed for urea by Liebig's volumetric process, which was repeated to insure accuracy. He was a very large man, passing copiously of urine, and the quantity thus arrived at was 540 grains; the total quantity of urine being 2000 cubic centimetres ($66\frac{2}{3}$ f $\bar{3}$). He was then ordered a hot-air bath daily, during which he perspired most freely. The twenty-four-hours' urine was of course diminished; but on estimating the urea in the twenty-four hours after the sweating had been continued three days, it was found to be 714 grains in 1700 cubic centimetres ($56\frac{2}{3}$ f $\bar{3}$) urine,—actually an increase over the amount secreted when not under the baths. This can be accounted for by the increased celerity of the circulation which would naturally result. If we add to this the amount of urea contained in the increased perspiration, which was of course not determined, on account of the difficulties of collection, we will perceive how powerful a means of depurating the blood of its urea is thus at our disposal; and I am quite certain that if the use of the hot-air bath were more common our power over Bright's disease would be greater. There is a common impression that it is troublesome and difficult of application. But this is not the case, as may be seen by the apparatus I exhibit, being that in use at the Philadelphia Hospital. Sometimes, however, these hot-air baths are not well borne by patients; they do not perspire, and the head and face become flushed, and the former throbs and aches. Under these circumstances the warm pack already described may be used instead.* It is perhaps equally efficient, but is more troublesome. It may be objected that these means are exhausting to the strength of the patient; but I think they will be found less so than is commonly supposed; the strength of the patient may, however, at the same time be maintained by iron, tonics, and milk.

The use of *purgatives* for depurative purposes and to reduce the dropsy has long been common in the treatment of chronic Bright's disease, and to this end it has been common to select a peculiar class of purgatives, viz., those which produce profuse watery evacuations, as elaterium, scammony, gamboge, and jalap. In addition to the indications to relieve general venous congestion with a view to promoting absorption, the advantage to be derived from the use of a brisk, prompt cathartic has already been alluded to in speaking of the treatment of acute Bright's disease. But it must be remembered that in the circumstances now under consideration it is not a temporary cause the effects of which we desire to obviate, but a constantly acting one, so that to be of service the purgative must be continued day after day, or every other day at least. Now, such use of the hydragogue cathartics above mentioned cannot be continued for any length of time without materially reducing the strength of the patient much more decidedly than through the daily sweat. I do not deny their effect in diminishing the dropsy. On the other hand, I have many times observed this effect, and in some I have observed the dropsy totally disappear,—but with it the strength of the patient to such an extent that as the dropsy subsided the life of the patient went out with it, so that it might truly be said that had the patient lived a little longer the dropsy would have been cured. I am not, therefore, very partial to the continued use of cathartics in chronic Bright's disease. But it must be remembered that it is to the prolonged use that I refer. To relieve a sudden emergency, as the occurrence of uræmic symptoms,—in a word, under the same circumstances under which I would use them in *acute* Bright's disease if they could be administered, would I give them. Of the remedies mentioned, undoubtedly the one which most strikingly produces the desired effect is elaterium. The profuse painless discharges which it effects in doses of one-twelfth to one-sixth of a grain are well known, while the small quantity required makes it peculiarly easy of administration.

But in most cases of chronic Bright's disease, except the chronically contracted kidney, a stage is finally reached at which all treatment of the kind described fails to relieve the dropsy, which becomes eventually the sorest burden of the malady. The body becomes greatly increased in weight, the integument of the extremities is stretched almost to bursting, and sometimes it does rupture, when it is attended by a leakage, which, although in one way inconvenient, is in many senses a great relief to the patient, by diminishing the tension referred to. Acting upon this, physicians have long been in the habit of puncturing the swollen parts to produce the required leakage. In my early experience I once had such horrible results in the sloughing away of the entire scrotum of a little child with scarlatinal nephritis, after I had punctured it, that I declared I would never repeat it. But as other cases came under my observation my prejudices thus excited gradually disappeared, and I now resort to puncture when it seems likely to give relief. It only remains to determine the best method of per-

* Since reading the paper, a member of the Society has suggested the propriety of tying a wet handkerchief about the head, as is done in the Turkish bath, with a view of preventing these unpleasant head-symptoms; and it is not unlikely that it would prove an efficient agent.

forming the operation. It is a common practice to make a number of minute punctures with a needle or sharp-pointed bistoury. Dr. George Johnson, of London, recommended making a free incision half an inch long, just above the outer or inner ankle of each leg, and deep enough to enter the areolar tissue beneath the skin. This may be done with a bistoury; but Dr. Johnson used an instrument mounted like a spring-lancet, which he recommends as more efficient and less painful than the repeated fine punctures. He relates an instance which is so remarkable and so admirably illustrates the possibility of recovery when the symptoms have reached an advanced stage, that it is quite worthy of re-narration. In July, 1861, he saw a clerk, aged 22, who had suffered from general dropsy since the end of March, after exposure to cold. The urine became nearly solid with acid and heat, while it contained *numerous oily casts*. Purgatives and diuretics failed to lessen the dropsy, and at the beginning of September the swelling was so great that the skin cracked and water oozed through the fissures. The legs were now incised; a copious discharge of water occurred, and the urine became more copious. From that time he steadily improved; the dropsy passed away, and gradually the urine ceased to be albuminous; but it was not until the end of April, 1862, more than a year from his illness, that all traces of albumen had disappeared. The chief medicinal treatment after the incision of the legs was the use of tincture of perchloride of iron three times a day, and a dose of broom-tea in the morning. Such recoveries as this are rare, while their possibility shows the value of hopeful perseverance in treatment. I have never seen the instrument referred to, but have made the large incisions with satisfactory results, although I can point to none so satisfactory as Dr. Johnson's.

With regard to specific methods of treatment, none are of any avail, and, so far as they ignore special indications, they are mischievous. I have heard of calomel being used for long periods to the production of its specific effects,—for what object, except to hasten the blood-dyscrasia which is the ultimate cause of death, I cannot say. It requires to be mentioned only to be deprecated.

The use of *opium* requires to be alluded to. The caution which has always been suggested in its use I believe to be in the main a wholesome one, and I should prefer to produce hypnotic, sedative, and antispasmodic effects by chloral and the bromides whenever it is possible. I am sure I have seen death accelerated in one case of previously unsuspected chronically contracted kidney in which large doses of opium were exhibited for another purpose,—overdoses, in fact, but quite insufficient of themselves to produce the fatal result, which was preceded by uræmic stupor. After death the urine was drawn by a catheter and found to be albuminous, and a post-mortem examination revealed a contracted kidney. On the other hand, I would not omit the use of opium where there was decided indication for its use to allay pain. It is well known that Professor Loomis, of New York, treats with apparent success cases of uræmic convulsions with hypodermic injections of large doses of morphia (one-half grain

or more),—doses which I would fear to use under ordinary circumstances in the absence of renal disease. A method, however, suggested by so high an authority as Dr. Loomis merits a trial, which I should be glad to give it under appropriate circumstances.

CROUP AND DIPHTHERIA.

BY JOSEPH G. RICHARDSON, M.D.,

Microscopist to the Pennsylvania Hospital.

ALTHOUGH the doctrine of the identity of these two diseases has been ably combated by my friend Dr. H. Hartshorne in the *Medical Times* for June 27, yet so pernicious does this error, as I deem it, appear to be, that I feel impelled to add a few words to his testimony. The obvious dissimilarities, and, indeed, contrasts existing between croup and diphtheria, are so evident in marked instances that I can only account for an observer of even average ability confounding them, by supposing that he has fortunately met with the latter malady infrequently, and then in a mild form and as a chiefly local manifestation. To one who has been called upon to treat hundreds of cases almost every winter, as I was obliged to do near my former residence in Cayuga County, New York, the mistake seems on any other supposition quite inexplicable.

In several of my fatal cases there was no croupy cough, no suppression of the voice, and no distressing dyspnoea,—death occurring from simple asthenia; in one of which I have notes, the hoarse cough, indicating the supervention of croup, came on only twelve hours before death, when the patient was actually moribund, and after the whole faucial region, and even the roof of the mouth, was thickly coated with false membrane; whilst in another, upon which I performed tracheotomy, the symptoms of croup supervened on the sixth day, ninety-six hours before the fatal issue.

The most conclusive example I can bring forward, however, is that of a child some three years old, who was treated so severely for diphtheria by rubefacients to the neck as to produce vesication. When the little patient succumbed, several days afterwards, the pharynx and larynx were *quite clear of deposit*, but the abraded surface around the neck exteriorly was *thickly covered with diphtheritic membrane*. I did not see this patient myself, but his condition was minutely described to me by three eye-witnesses, viz., the father of the child, the irregular practitioner in attendance, and a neighbor who sat up with the little sufferer, and who, by the way, took the disease, and was very ill with it under my care for more than a week, but finally recovered. I am satisfied that the affected infant presented the phenomena just narrated, and have always felt we could hardly hope to obtain a more conclusive proof of the difference between pseudomembranous laryngitis and true uncomplicated diphtheria.

The characteristics upon which my experience has taught me to rely chiefly in making a differential diagnosis between these two maladies are, besides

the aspect and seat of the false membrane,—1, the astonishing and immediate prostration of strength in diphtheria; this I have seen profoundly marked before any throat-affection was manifest; 2, the comparatively low temperature, as detailed in my paper on Diphtheria, in the *New York Medical Record*, quoted by Flint in his *Practice of Medicine*, p. 940, and Wunderlich, *Clinical Thermometry*, p. 368; 3, the strong contagiousness of diphtheria, which I have seen exemplified in scores of instances; 4, the fact that diphtheria is common in adults, whilst croup is extremely rare; and 5, the therapeutic test of the remarkable control which chlorate of potassium and tincture of chloride of iron exercise upon most cases of diphtheritic complaints. Lastly, the subsequent appearance of the curious forms of diphtheritic paralysis may enable us to solve the problem in some doubtful cases.

1835 CHESTNUT STREET, Philadelphia.

NOTES OF HOSPITAL PRACTICE.

KING'S COLLEGE HOSPITAL, LONDON.

SERVICE OF SIR WILLIAM FERGUSSON, BART.

Reported by JOHN B. ROBERTS, M.D.

TENOTOMY FOR THE RELIEF OF TALIPES EQUINUS.

THIS boy, aged 16, presents a well-marked case of a very common distortion of the foot, namely, talipes equinus; that is, the heel is drawn up, and he walks upon his toes. Deformities of the lower extremities have, no doubt, always been common, but the remedy is of recent date, for it is not many years since the operation of tenotomy for the cure of club-foot was looked upon as a great novelty and was the source of much curiosity. In this instance, as you see, the left heel is drawn up and the foot turned somewhat inward, while the toes, especially the first and fourth, are pulled up by the extensor muscle. At the same time the calf of the left leg is smaller than that of the right, and has a wasted appearance.

It would appear as though the tendo Achillis were at fault in these cases; but this is not necessarily so, for the distortion is probably due to the calf-muscles, and not to a short tendon, though in the treatment we usually divide the tendon in order to let the heel come down.

In this case, the tendons of the extensor digitorum shall first be divided, to allow the toes to be straightened, which is readily done by introducing the tenotome and cutting subcutaneously the tendon going to the great toe and that of the fourth toe, since the other toes do not demand the operation. Then the foot is grasped by the assistant, who makes the tendo Achillis tense, and the knife of the operator introduced flatwise is turned against the tendon, which is cut with a snap. This allows the foot to be pulled into position, and there can be felt as much as an inch of space between the two ends of the severed tendon; which interval will subsequently become occupied by analogous tissue uniting the parts.

The tendo Achillis is very often divided; but this case is somewhat different from usual instances, in that the extensors of the toes had to be cut, an operation not often required, though a very valuable procedure in certain classes of distortion. A pad is now placed over each puncture, and secured with adhesive strips, after which the whole foot is surrounded by a bandage.

SERVICE OF MR. HENRY SMITH, F.R.C.S. TREATMENT OF HEMORRHOIDS BY THE CLAMP AND EXCISION.

This woman, when she entered the hospital, presented a very bad case of internal hemorrhoids; but to-day the tumors are smaller and less inflamed, because she has been kept quiet in bed for some time past. Nothing short of some form of operative procedure will relieve her; and therefore the tumors shall be excised.

A leather band is buckled around her right wrist, and another to her foot, one band having a ring, the other a hook attached. The leg having been bent, the two bands are hooked together, thus holding the limb out of the way during the operation. The finger, introduced into the vagina, turns the hemorrhoids out of the anus so that they can be grasped by the forceps. When this is done, the ivory clamp is applied to the mass and screwed up, then the tumor is cut off with the scissors, and the actual cautery applied to the cut surface to seal up the vessels before the clamp is removed. Another mass is drawn forth, and the clamp applied, but, being small, it is merely seared with the iron without being excised first.

This having been done to three separate masses, an opium suppository is introduced. The bowels shall be kept quiet for four days, after which a cathartic shall be given; and in a week the patient will probably be discharged from the hospital.

This operation for the cure of hemorrhoids is simple, safe, quick, and effectual. The clamp consists essentially of two flat pieces of ivory arranged like a pair of scissors, with a screw which holds them firmly together when the pile has been seized between their edges. The object, of course, is to prevent hemorrhage after the excision, and to protect the adjacent parts during the application of the cautery. By this method the ordinary dangers of the operation are avoided, for hemorrhage is prevented, and there is no danger of pyæmia, because the mouths of the vessels are sealed up by the cautery.

In four or five hundred operations Mr. Smith has never had a case of pyæmia, and has never been obliged to plug the rectum for hemorrhage.

It has been asserted that stricture is likely to follow this operation. This might be so if a large portion of skin were cut away; but only the mucous membrane should be excised. Mr. Smith has never seen a case where stricture followed; and in one case, where, after death from another cause, an examination was made, no stricture whatever was found. In those instances in which it is necessary to excise a large portion of the skin, it is well to use the bougie to dilate the orifice during the after-treatment, and thus to prevent the occurrence of contraction.

IMMOVABLE APPARATUS IN ACUTE ARTICULAR RHEUMATISM.—Dr. S. Scapari concludes from his experience that immovable apparatus made either with plaster of Paris, silicate of potassium, or starch, are exceedingly useful when applied to the affected joints in acute articular rheumatism, although they certainly have no influence upon the disease itself. If on the appearance of the first symptoms these applications are made to all the joints, sound and affected, they seem to exercise an abortive effect, preventing the appearance of the affection in some of the joints, and calming and arresting the manifestations already developed in others. Dr. Scapari even goes so far as to assert that the spread of the disease is diminished, as well as the probability of concomitant complication on the part of the serous membranes, the heart, and the lungs.—*Bull. Gén. de Thérap.*, No. 10, 1875; from *Raccogliore Medico*, No. 3, 1875. X.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 10, 1875.

EDITORIAL.

CHEAP JOHN.

WE once heard an anecdote of a celebrated German millionaire who, when asked at a dinner in London to select between some tempting Southdown and a fine haunch of venison, curtly replied, "I never takes the deer when I can have the *sheep*." Our medical confrères across the Alleghanies evidently endorse the above views.

Some attentive friend has sent us a flaming annual announcement and catalogue of the Missouri Medical College, Session 1874-75, cover "couleur de rose," full of promise, we will hope with no lank performance.

This announcement savors of the modern display-advertisement style, and we looked for the mysterious four-leaf clover with which a certain ingenious firm inveigle the *imberbis juvenis* of our country. We have no doubt that the opportunities for clinics, the material for medical instruction, are all that are vouched for in this unique circular. We say circular, for the advertisements of certain hotels and peculiarly-colored passenger-cars induce us to fear that our shrewd confrères, to diminish the expense of the printer, have entered into a compact with certain proprietors of hotels and stockholders of passenger-cars. This, however, is only *business*. Our heartfelt, earnest protest is against the cheapening of medical education, of which this announcement is a remarkable characteristic:

"The faculty have for thirty years maintained the old fee of \$105. They have done this up to

last year, notwithstanding the schools in every other city west of the Alleghanies reduced them years ago. At a recent meeting of the representatives of the faculties of many of these schools, in Detroit, the Missouri Medical College again advocated the old rates, but the schools which first reduced them declined to make any change. In reducing the fee, the faculty have placed the superior advantages of this school in reach of many who have hitherto been deprived of them by pecuniary considerations. They, therefore, do so *cheerfully*, and at a time the most prosperous in the history of the College. Fee for full course of lectures, \$50."

O tempora! O mores! Such are the results of twenty years' labor of the American Medical Association! Such is the trans-Alleghany endorsement and appreciation of the untiring, self-sacrificing efforts of one of the oldest medical colleges of our country to double her corps of professors, to increase the number of her chairs, to raise the standard of preliminary examinations, to extend her curriculum,—in other words, to raise the status of the medical profession, and to send forth sound physicians, polished gentlemen, conscientious men.

In the dim future, should our Western brethren still persist in their levelling propensities, we may look forward to an annual announcement of some medical school appended to Jayne's Almanac, with the following programme:

"THE OI POLLOI MEDICAL COLLEGE, SESSION
 1884-85.

"Anatomy, physiology, practice of medicine, surgery, obstetrics, and materia medica at prices to suit the times.

"Dissecting-room tickets half-price; babies alone dissected. Hospital and quizzes gratis.

"Tickets to the college, in yellow-colored cars, gratis. Meals provided at the 'Great Hygienic Hotel,' in Red Lane.

"Students forming clubs of ten taken at reduced prices. Married students are permitted to substitute their wives as attendants upon the lectures at their option. Students may still further diminish their expenses by offering themselves or members of their families, when indisposed, as subjects for the clinics. Should any student fail to pass his examination, fee refunded. The faculty, however, pledge themselves never to place their candidates in so embarrassing a position. Prof. Shrewdem will, at his convenience, give a lecture on the American view of the Monroe doctrine, in opposition to the late Professor Munro, of England."

"Spectatum admissi risum teneatis, amici?"

LEADING ARTICLE.

THE VIENNA TREATMENT OF UTERINE HEMORRHAGE.

DR. CARL v. ROKITSKY, Jr., may fairly be regarded as a representative of the German, or at least of the Vienna, school of gynecology. If we examine, therefore, his most recent utterances on the subject,* we may expect to get a reasonable idea of what advances our German brethren are making in the treatment of this class of affections, and wherein their methods differ from our own.

Two indications for treatment in general are pointed out by Dr. Rokitsky: first, to stop the excessive hemorrhage of the moment; second, to prevent its return. The general treatment to fulfil these indications must consist in the exhibition of repressive medicaments and in the administration of a proper regimen, while the local therapeutics should be directed towards a pharmacæutic effect upon the vaginal or uterine mucous membrane on the one hand, and against the exciting causes of bleeding in the uterus on the other.

One of the most important points in the treatment of uterine hemorrhage is rest,—rest in the horizontal position, with raised hips, the coverings not too warm, no movement, not even in emptying the bladder or rectum. All excitement is to be avoided; the food and drink are to be of the simplest character: roast meat and ice-cold soda-water are the best nourishment. The chamber should be kept at an even temperature and supplied with plenty of fresh air. Everything which can cause congestion of the pelvic organs is to be avoided.

In what is called active uterine hemorrhage, particularly metritis hæmorrhagica, cold in all forms is to be avoided, because, while its transitory application tends to cause congestion, its continuous employment is not to be thought of. The application of frequently-changed cold compresses to the abdomen is, however, to be recommended. In these cases the plentiful application of leeches to the lower portion of the abdomen, or even to the vagina itself just before the menstrual period, is often extremely effective. In light cases these means, combined with mild laxatives and tonics, will place the patient in an improved position; and these precautions should be taken by all women liable to hemorrhage at the menstrual period.

In menorrhagia, which is simply the expression of general debility, marked improvement follows the use of tonics, and particularly preparations of iron. When the loss of blood is not due to uterine disease, improvement of the skin's action, strengthening of the general health, and regulation of the bowels aid greatly in the cure. A systematic course of hydro-therapeutics is often of great benefit in these cases. In all severe cases of profuse hemorrhage, which tend rapidly to anæmia, it is indispensable, during the intervals, to stimulate the strength of the patient to the utmost degree possible.

In what is called passive hemorrhage, which is by far the most usual form of profuse menstruation, and which, by lasting weeks, or even months, brings the patient almost to dissolution, cold may be used with propriety. This means, however, frequently fails, and the physician is constrained to employ pharmaceutical or occasionally mechanical applications to the uterine mucous membrane. The medicaments used for this purpose are astringents, or more usually caustics. These are used in the solid or the fluid state. The use of powders has been of late almost entirely given up. Of the various medicaments, none can replace nitrate of silver. The others are usually tardy in their action, and often produce untoward symptoms (as the uterine colic brought on by the mixture of alum and sulphate of copper).

Whether or not the speculum is used in making these applications, their use should always be preceded by examination with the uterine sound, in order to ascertain as exactly as possible the situation, the condition, and the irritability of the uterus.

Dr. Rokitsky recommends the use of the lunar caustic in considerable quantity: if a small piece is used it is wasted in coagulating the blood, and does not reach the mucous membrane itself. He never uses the caustic until the cervix has been dilated. Slight pain is caused by its use, which usually lasts only a few minutes, occasionally an hour or so. Nausea, and even vomiting, may occur. Very exceptionally the pain may last a day or so, or give rise to feverishness. Dr. R. has only in a single case observed the supervention of dangerous symptoms. One precaution should be observed, particularly in walking cases,—that is, not to cauterize too energetically the first time. The irritability of the uterus should first be tried, and if there is a tendency to uterine colic it should gradually be accustomed to the application.

As to the method of applying the caustic: after the cervix is dilated sufficiently, and the uterine axis brought as nearly into a normal position as possible, a stick of caustic, perhaps an inch long, is introduced by a sidewise motion, either by means of forceps or on the end of a quill from which, after the caustic is placed in position, the latter is broken off. The introduction must be rapid, or the inner cervix may close before the caustic is completely introduced.

A cylindrical speculum of hard rubber is preferred by Dr. Rokitsky, who advises also that no effort be made at forcing it into position. If, for any reason, this cannot be employed, a "porte-caustique" or "uterus pistole" may be used. In most cases cauterization one, two, three, or four times every second, third, or fourth day will control the hemorrhage. Relapse may be prevented by the use of extract of ergot. Digitalis, tincture of cannabis Indica, rue, savin, etc., are nearly useless.

Two methods of cauterization with fluids may be used: either cotton-wool soaked in the medicament and introduced by any of the ordinary instruments through a rubber speculum, or intra-uterine injection. The latter method is highly praised by many authors, who, at the

* "Ueber Gebärmutterblutungen und deren Behandlung," *Wiener Klinik*, 1 Jahr., 4 Heft, April, 1875.

same time, warn against the evil effects which may easily follow. The best guarantee against such effects is the continuous patency of the entire cervical canal, and this can best be obtained by previous dilatation with sponge tents or laminaria. This of course allows free exit to the injected fluids, and prevents the danger of their being forced into the Fallopian tubes. In addition to this precaution, it is necessary to inject no more than three, four, or at most six drops at any one time, and to inject only very slowly, and drop by drop. By this means the danger is reduced to a minimum.

These injections, as well as any kind of cauterization of the uterus, are to be avoided only when there are inflammatory processes in the uterus or its adnexa, or in its immediate neighborhood. Version or flexions of the uterus are not to be regarded as contra-indications, but call for the greatest care. Among medicaments, neutral liquor ferri sesquichlor. and tincture of iodine are the best.

When the porte-caustique is used, the patient should lie on her back, with the hips elevated. In making the application by other means, the position may be any of those usually taken. The vagina should be protected by a tampon of cotton-wool slightly impregnated with glycerin.

Recently injections of hot water have been recommended in post-partum hemorrhage by Dr. Windelband; but these have not yet been fairly tried.

Among the mechanical means of arresting hemorrhage, the sponge tent is the most prominent. For instance, if the usual means of controlling uterine hemorrhage fail and a polypus is suspected, the first thing to do is to dilate the cervix and make an examination. Occasionally the use of the tent a single time will in itself put an end to the bleeding; and if the pressure is directly upon some excrescence, this may disappear, removing at once the hemorrhage and its exciting cause.

Dr. Rokitansky only uses the sponge tent in cases of extreme necessity, and never leaves it longer than six, or at most eight, hours in position.

As to tamponing the vagina with cotton, charpie, etc., impregnated with liq. ferri sesquichlor., this procedure rarely has any lasting effect; and if these tampons are left too long in position, infection, or at least local irritation, may result. Colpeurynters filled with ice-water are better; but where the physician is suddenly confronted with immediately threatening hemorrhage, tamponing as above may be an absolute necessity.

In cases of uterine fibroid when removal cannot be performed, dilatation of the cervix with injection of tinct. iodinii may prove serviceable.

Finally, the hypodermic injection of ergotin is very useful when the hemorrhage proceeds from uterine fibroid.

When the cause of hemorrhage is to be traced to poly-poid growths, these must be removed, if they can be reached by instruments. When they are not attainable, injections of ergotin and the cold douche may be used. Dilatation of the cervix by sponge tent is not to be resorted to unless the strongest necessity exists. Cancerous

growths are to be removed by the galvano-cautery, the sharp spoon, or the actual cautery, followed, when the eschar falls, by Wynn Williams's solution (one part bromine to five parts alcohol). When cancerous nodules still remain after this last operation, the bromide solution may be injected directly into the parenchyma of these tumors.

CORRESPONDENCE.

NEW YORK, June 25, 1875.

A REMARKABLE case of aortic aneurism has lately attracted considerable attention at the Roosevelt Hospital. The patient was a German, 40 years of age, a stevedore by occupation, and admitted to the hospital for the first time in August, 1874. Seven months previous to this date he had fallen through a ship's hatchway, striking upon his back, and probably receiving some internal injuries. He complained of severe pains in the chest, but there was no evidence of any spinal trouble, so far as could be ascertained. After a few days' rest he was able to return to his usual avocation; but in a short time he was obliged to give up continuous work. Up to the time of his admission, however, he was still able to work for a day or two at a time occasionally. When first examined, a distinct tumor was found in the region of the first and second costal cartilages, on the right side, and he complained of constant pain about the sternum and between the scapulæ, behind.

He remained in the hospital, without much change in his condition, until November 9, when he was discharged at his own request. He was re-admitted February 13, 1875, having continued to suffer during the interval from severe shooting pains in the anterior portion of the chest, and a dull, burning pain in the upper part of the spine. The tumor had somewhat increased in size, and a distinct thrill could now be detected in it. About the 1st of June its upper surface began to grow red and tense; and on the 13th it broke spontaneously, and discharged a considerable quantity of pus mixed with dark-colored blood.

On the 19th, the discharge of purulent fluid was enormous, and the patient was rapidly becoming exhausted. About three o'clock that afternoon there was a rupture of the aneurism beneath into the superficial alveus. The house-physician immediately applied a compress, and summoned Dr. Weir, the visiting surgeon, who happened to be in the hospital at the time. By forcible compression with oakum saturated with persulphate of iron solution, the hemorrhage was entirely controlled in about fifteen minutes; but, as the patient's pulse was 144 and his exhaustion extreme, his death apparently could be only a matter of a few hours at the farthest. His condition, however, afterwards improved, temporarily, so that he actually lived until 5.30 on the morning of the 21st.

The autopsy was made the same day, in the presence of Drs. William Draper (in whose service the case occurred), Erskine, Mason, Weir, McBurney, and others.

The heart was found not to be greatly displaced, the apex being about two inches to the left of the median line. This was probably owing to the fact that the left lung was everywhere bound down by firm adhesions. The left pleural sac contained about one and a half pints of sero-purulent fluid. The whole arch of the aorta was found to be affected. Just to the right of the origin of the innominate artery an opening of the size of a small pipe-stem was seen, communicating with an alveus under the sternum; and this had, no doubt, been the immediate cause of death. At a point corresponding to this, the manubrium of the sternum was very badly eroded. The original or main aneurismal sac was situated in the transverse portion of the arch, and on its lower aspect, just opposite the mouths of the innominate, left common carotid, and left subclavian arteries. These arteries were not compressed or affected in any way, and thus the marked regularity of the radial pulse on both sides, which had been noticed, could be accounted for. The distended cavity of the aorta at this point would probably have admitted a moderate-sized foetal head. The sac was filled with soft clots, and over the greater portion of its internal surface old layers of fibrin were deposited. Its walls were everywhere thick and firm.

The descending portion of the arch was so firmly adherent to the vertebræ that it was much lacerated in removing it from the thorax. There were extensive caries and erosion of the second, third, and fourth dorsal vertebræ, and of the corresponding ribs; one of the latter being almost entirely eaten through. The right lung, except being somewhat œdematous, was normal. The left bronchus had been strongly pressed upon, and a section of the left lung showed that it was firmly compressed, and everywhere riddled with abscesses, there being several cavities in it of the size of a walnut.

It is certainly very remarkable that a man should live for thirty-six or thirty-seven hours after the opening of an aortic aneurism; but this is less to be wondered at when we remember that the perforation was caused by ulcerative action, from the external abscess, and not by a proper rupture of the sac, from progressive thickening of its walls; which, of course, almost always necessarily results in instant death.

A month or two ago, a patient at Bellevue is said to have lived for twelve hours after the rupture of an aortic aneurism; but we are not acquainted with the facts of the case.

Since the date of our last letter, the Harlem Flats nuisance has occupied a still greater share of public attention. The white-washing report of the police surgeons has been repudiated by several others of their number, and innumerable have been the petitions, meetings, resolutions, investigations, and letters, to say nothing of the conferences of mayor, aldermen, health commissioners, and commissioners of public works, in regard to the matter. As a result of all this, it was hoped that the grand jury would take some action; especially after a protest had been presented to them, signed by a large number of physicians practising in

the neighborhood of the infected district, and confirming the worst that had been said of the baneful influences of the refuse deposited on the flats; but they declined to interfere in the premises.

Still, the filling-in with refuse matter has been stopped, and the commissioner of public works requested by the board of alderman to cover the flats with a thick layer of pure and wholesome earth.

In the mean while, the health department has been endeavoring to disinfect the pestiferous region with copperas and "dead oil" from the petroleum works at Hunter's Point; but as it is almost a herculean task to deodorize a deposit extending over such a large area, which to a large degree consists, according to reliable medical authority, of apples, oranges, turnips, carrots, pea-shells, potato-peels, hay, straw, manure, and dead dogs and cats, the odoriferous stench still smelleth unto heaven, if one can believe the reports of the unhappy residents of the vicinity.

It is gratifying to know that some of the churches here have been taking up collections for a "fresh-air fund," to provide for short excursions by land or water for the poor during the summer, and a residence of one, two, or three weeks out of the city for those who are most enfeebled. The lead in this matter has been taken by the rector of the Anthon Memorial Church, Rev. Heber Newton, son of Dr. Richard Newton, of Philadelphia, and it is his aim eventually to establish a permanent summer home for the worthy poor, under the auspices of his church.

Nearly \$11,000 has been contributed towards the Floating Hospital of St. John's Guild, but \$20,000 is needed to complete a barge capable of accommodating twenty-five hundred sick children and mothers. In a recent appeal to the public, the trustees say, "No plan for the relief of the sick children of the poor has more practical advantages than the proposed hospital barge. The pure, invigorating sea air, wholesome food, medical attendance, kind nursing, roomy quarters, and healthful recreation, are, through this method, placed at the disposal of both mothers and children, and the time so arranged that the necessary household duties will not be infringed upon. Over fifteen thousand children and mothers were taken out on the eighteen excursions given by the Guild last summer, while hundreds had to be refused for want of the necessary accommodations, which the present effort is intended to remedy. Now the work is to be carried out on a larger scale, and with results, it is hoped, that will tell beneficially upon the health of the entire city."

As a result of the joint meeting of the Public Health and Dwelling Reform Associations, at which Dr. Stephen Smith advocated the increase of suburban homes for working-men, a committee, consisting of Mr. Parke Godwin, Hon. D. B. Eaton, Prof. C. F. Chandler, and Dr. Smith, has addressed a circular letter to the presidents and directors of railroads radiating from this city, to urge the inauguration of a system of cheap morning and evening trains for working-people.

The Park Hospital, near the City Hall, having been

abandoned on account of the insecurity of the building, there is now no adequate house of relief for cases of sunstroke and other accidents in the lower part of the city; and, in view of the advent of hot weather, the Governors of the Society of the New York Hospital have requested the Mayor and Sinking Fund Commissioners to appropriate one of the late station-houses in Beekman or Chambers Street for such a hospital, promising to fit up the building, as well as care for the patients received, at their own expense.

Notwithstanding the energetic labors of the extra corps of vaccinators appointed by the Board of Health, smallpox still continues to prevail, one hundred and twenty-eight cases having been reported during the week ending June 29. The smallpox hospital on Blackwell's Island is entirely filled, and, in addition, quite a number of tents have been erected outside for the accommodation of convalescents. Diphtheria also continues epidemic in the city, over a hundred cases being reported for the same week.

The managers of the Presbyterian Hospital seem at last to appreciate that the profession is in earnest in its demand for an explanation of their late extraordinary action, and have called a special meeting of their board to take into consideration the present state of affairs. Not only have the four newly-appointed physicians resigned, but almost the entire staff of visiting physicians and surgeons are also said to have handed in their resignations.

PERTINAX.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 22, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Sponge-like bodies from synovial cyst in a cow.

DR. J. C. WILSON presented a number of small bodies evacuated by the spontaneous opening of a large synovial sac on the leg of a cow. These bodies were irregularly spherical in shape, and ranged from a quarter to a half inch in diameter. They looked like small pieces of soft, white sponge. The cyst which contained them was a large one, and had existed four years, without, however, producing lameness. It burst whilst the animal was in the stable, and the quantity of these sponge-like masses that fell out amounted to a quart. A little clear gummy liquid escaped with them. When fresh, they had a strong alkaline odor.

THURSDAY EVENING, MAY 13, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Double monster.

DR. LOUIS A. DUHRING presented, for Dr. E. E. MONTGOMERY, a double monster, described in the *Philadelphia Medical Times* for May 1, 1875.

Aneurism of the abdominal aorta.

DR. W. G. PORTER presented the specimen, obtained at a post-mortem which Dr. P. made for a fellow-practitioner about three weeks ago. The history was as follows:

"He was called to see the patient, a man about fifty-

seven years of age, about a week before his death, and found him suffering from tympanitic distention, colicky pains, constipation, and vomiting. Under treatment the vomiting and constipation were relieved, but the tympany, though somewhat modified by treatment, still remained, and the patient, who was an old drunkard, sank, and died exhausted."

Post-mortem.—The whole aorta from the heart downwards was the seat of extensive atheromatous change, the artery feeling more like an egg-shell than anything else. Just below the diaphragm a large aneurism was found, almost filled with laminated fibrin; it had eroded three of the vertebræ, and, rupturing on its posterior aspect, had formed a large false aneurism, and had filled the whole of the left side of the pelvis.

Multiple cavernous angioma of the liver.

DR. R. M. BERTOLET presented the specimen, and furnished the following history:

"This unusually fine specimen, unique among the presentations to this Society, was removed from Patrick S., a laborer, æt. 50, a native of Ireland. He died upon April 30, two days after his admission into the medical wards of the Philadelphia Hospital. He was carried off by an acute croupous pneumonia of the right upper lobe; during his illness there was no hepatic tenderness, nor any jaundice, or other symptom manifested to call especial attention to the liver.

"The autopsy, however, disclosed six large dark-bluish spots of considerable size, some of them measuring over an inch and a half in diameter, scattered through both lobes of the liver. These growths are seated in both the anterior and posterior surfaces, most abundantly towards the lower free margin. Their conical or wedge-shaped appearance upon section, as well as their peculiar coloration, led them to be mistaken upon first sight by the resident physician for hemorrhagic infarctions. This mistake is, no doubt, frequently made, since the liver is unquestionably the most favorite seat for these tumors; yet in this site they so far remain unrecorded in our proceedings. A careful inspection with the unaided eye, however, suffices to show that they are actual new growths, with a thin, whitish, reticulated net-work running through them and forming small angular meshes, the cavities of which are filled with dark, coagulated blood; the whole giving to the cut surface an appearance not unlike the alveolated structure of the lungs. The blood can be readily squeezed out from the spongy, cut surface, when the reticulated structure becomes still more evident. In this specimen the tumors, although most of them are directly under the capsule, do not project or bulge above the general level of the surface, excepting one of the largest, which is seated in the lower border, and there presents slight elevations both upon the anterior and posterior surfaces. The centre of each growth further presents a dense, broad band, looking not unlike an obliterated and thickened blood-vessel.

"Formerly, the term '*fungus hæmatodes seu spongiosa*' was applied to these growths, but it has also been bestowed upon cancerous, sarcomatous, and other malignant tumors whenever they presented an unusually vascular appearance, thus leading to much deplorable confusion. Virchow was the first to designate those growths as *angiomas* which are formed by a hyperplasia and ectasia of the capillary loops of the blood-vessels in a circumscribed locality. When, as always happens in the liver, these vessels are so distended as to form large sinuses or mere vascular spaces, then we have presented a structure the physiological paradigm for which is found in the corpus cavernosum of the penis, and which is now designated as the *cavernous* form of angioma.

"Microscopically, the accompanying slides present

an appearance so closely corresponding with the admirable delineation given by Frerichs* that I doubt whether a more accurate drawing for these specimens could have been made. Under higher powers, it becomes evident that the vascular spaces are lined with a single layer of endothelial cells; while the meshes are seen to consist of a dense fibrillated connective tissue, with few cellular elements. Smooth muscular fibres and a certain amount of elastic tissue also aid in forming the bulk of the whitish septa. Enormously dilated blood-vessels, whose thickened walls together with connective tissue form the irregularly-shaped meshes, may, therefore, be said to constitute these tumors. The peripheral portions are by far the most interesting, for we are enabled not only to observe how the adjacent hepatic cells undergo fatty metamorphosis and gradually disappear under the encroachments of the tumor, but here, also, the actual steps in their development can be readily studied. The larger growths in this specimen are not surrounded by well-defined capsule, as sometimes happens, and as is the case in the numerous small cystic angiomas to be referred to presently; but there are seen, here and there, bands of connective tissue extending between the acini. These bands, both in position and appearance, resemble the cicatricial tissue observed in advanced cases of cirrhosis, with this difference, that the one is circumscribed, while the other is diffused.

"The offsets from these angiomas are extremely vascular; even in them the capillaries are beginning to widen. This teleangiectatic condition is also possessed in common by the cirrhotic tissue, as has been recently pointed out by Cornil† and Rindfleisch.‡ A localized interstitial hepatitis is, therefore, the preliminary process, while the granulating connective tissue formed thereby, being unusually rich in blood-vessels, presents the most favorable conditions for the subsequent development of the angiomatous growths. This predisposition to the formation of sclerotic tissue is, in this specimen, certainly a localized one, for sections made through the hepatic tissue at some distance from the tumors fail to reveal even the earliest stages of indurative interstitial hepatitis.

"From injections that I have formerly made upon other specimens of hepatic angiomas, I am fully convinced of the correctness of the disputed statement that they can be filled only from the branches of the hepatic artery and portal vein, and that the lumen of the branches of the hepatic vein becomes compressed and obliterated. The multiplicity of these growths is a very ordinary occurrence, but it is extremely rare for them to attain the size of a walnut,§ which is certainly exceeded by several of the tumors in this specimen.

"The interest in this liver, in addition to the tumors already mentioned, is heightened by the presence of numerous (I have counted over fifty) small cystic formations. These vary in size from that of a pin's head to a small pea. They are generally filled with fluid blood; have a distinct limiting capsule; are clothed with endothelium, and frequently present slight ridges upon their interior surfaces.

"These cysts are scattered over the entire surface of the organ, and but few of them are concealed beneath the surface. Their endothelial covering, alongside of their contents, indicates their origin from the blood-vessels, perhaps by simple dilatation, but more probably also by the atrophy of the septa, the remains of which are seen as ridges upon the inner walls. Such an interpretation has been given by R. Volkmann,|| in

a case of *angioma cavernosum hamatocysticum nymphae*, and I think can also be accepted here. The minuteness of some of these cysts led me to hope that it would be possible to ascertain in what part of the territory of the acini they first begin to develop. Unfortunately, this could not be definitely determined in the absence of any injection, which had been rendered impossible by previous mutilation.

"Clinically, it is, of course, impossible to diagnose these hepatic angiomas, and Frerichs states¶ that he knows of no case in which they have given rise to local or general disturbances. Angiomas sometimes, however, lead to the development of melanotic sarcoma, and then become highly malignant, a by no means rare occurrence when they are seated in the skin."

The PRESIDENT believed that the specimen was the first one of angioma of the liver ever presented to the Society,—at least with a definite description of the lesion. It is very rare, at least, to find multiple lesions of this kind. He was able to recall two cases, in both of which the tumor was at the border of the liver, and triangular in shape. One was at least two inches in diameter, the other smaller, but both projected beyond the surface of the organ. The resemblance to hemorrhagic infarctus was more superficial than real, as the surface on a fresh section reveals to even slight examination the characteristic reticulum.

Dr. BERTOLET said that eight days ago he had met with a single angiomatous tumor in the liver, also in a male subject of advanced years. Out of an equal number of post-mortem examinations, he thought they were more numerous in a late than in an early period of life. He recalled but one or two cases recorded where there were any decided projections from the surface of the organ; but, as a rule, the seat was somewhat depressed. Those which caused a protuberance were seated in the lobus Spigelii.

The PRESIDENT replied that the protrusion was not excessive; but in passing the hand over the convexity of the liver it was appreciable. He thought that the surface of the growth was one-third of an inch above the surface of the hepatic tissue. The reticulum was very loose, and the meshes exceedingly large.

Chylous fluid from a hydrocele.

Dr. H. LENOX HODGE presented the specimen, for Dr. C. H. MASTEN, of Mobile, Alabama, who furnished the following history:

"It may prove interesting to the members of the Pathological Society to examine the accompanying specimen.

"The history of the case is briefly as follows: W. H. W., a native of Mobile, aged 22 years, robust in health, five feet eleven inches high, one hundred and fifty-seven pounds in weight, bilious temperament, black hair and eyes, dark complexion, presented himself on the 18th of October, 1874, to be treated for 'hydrocele.'

"He stated that some eight years ago he had first noticed an enlargement of his scrotum, which, however, did not give him any inconvenience, and that it was not until about four years ago that he considered it necessary to seek medical advice upon the subject. Then he was 'tapped' by his medical adviser, and (to use his own language) 'a quantity of milk was drawn out.' Subsequently he was tapped on several occasions, but no treatment instituted for a permanent cure. To satisfy myself of the nature of his affection, I at once introduced a trocar, and, to my astonishment, I drew off f3viii of a white fluid, which, to all appearances, resembled 'milk.' As the case was a novel one, at least to me, I concluded to send a specimen of the fluid to my friend Dr. James Tyson, of Philadelphia, for his examination and opinion.

§ Virchow, Geschwülste, Bd. iii. S. 392.

|| Archiv f. Klin. Chirurgie, Bd. xv. p. 568.

¶ Leberkrankheiten, Bd. ii. S. 214.

"The following extract from his letter, of date Philadelphia, October 25, 1874, gives the result of his examination:

"The specimen is alkaline in reaction, sp. gr. 1015, highly albuminous, and appears to be made up, as determined by microscopic examination, of innumerable molecules, which are mere points under a power of four hundred diameters, together with a limited number of small granular cells, somewhat smaller, but otherwise resembling the colorless corpuscles of the blood, floating in a serous fluid.

"Its physical characters are precisely those of *chyle*. Chemically, I find it almost completely dissolved by ether, and, after evaporation of the latter, to leave a cream-like mass. There were no spermatozooids whatever.

"The fluid is not only in its physical but in its chemical characters comparable to chyle, and I believe its origin to be similar to that of chylous urine so called, which is probably due to the leakage of a lymph-vessel into the bladder."

"So here there is, probably from some cause, a similar leakage from a lymphatic into the hydrocele sac. . . . A similar case is reported by Vidal, and called "galactoele."

"Our fluid was not examined for sugar; but, even with sugar present, I should compare the fluid to lymph or chyle, rather than milk, for it contained—

"1st. The *molecular base*, with very few oil- (milk-) globules.

"2d. The leucocytes, or chyle-corpuscles.

"3d. The albumen.

"Signed,

JAS. TYSON."

"Without speculating upon the case, I will simply state that I did not see my patient after the date upon which I evacuated the sac until the 1st of the present month, when he presented himself again, and requested that some operation should be done for his permanent relief, as he was contemplating a matrimonial connection and wished to be fully prepared for the occasion.

"The outlines of the operation I will mention, for the condition of the parts (as revealed by the operation) proves the correctness of the suggestion made by Dr. Tyson.

"On the 5th of April I cut down upon the sac, and then evacuated its contents through a canula. I found the same character and quantity of fluid as on the former occasion. After having discharged its fluid contents, I split open the sac and carefully examined its entire internal surface, for the purpose of detecting, if possible, the cause of the peculiar fluid. At the upper portion of the sac, just where it begins to be reflected backwards over the testicle, I discovered a small glandular-looking body, about the size of an ordinary pea, having very much the same appearance as the pouting granulations we often see at the opening of a fistula. The sac was very much thickened, and as dense and firm as the ball of an ordinary Davidson's syringe; it was smooth and polished on the inner side, showing no appearance of vessels. Slicing off this little body with a pair of scissors, I at once saw the mouths of some three or four vessels, *which did not bleed*, and which I believe were the mouths of the lymphatics, which had poured out this fluid.

"I dissected them back for a short distance, to see if they had any connection with either the cord or the gland, but found they were lost in the cellular tissue which surrounds the tunica vaginalis. I carefully tied the bunch of vessels with a small silk ligature, and brought one end out. Then, having cut away the front wall of the thickened sac, I coapted its edges with some four or five delicate silk sutures, bringing to the outside a free end of the suture, and then closed the wound in the integuments with the pin-suture, ordered

cold-water dressings, and left my case to heal, as I hoped it would, by primary union.

"On the fourth day I removed the pin-sutures, and found the wound in the integuments thoroughly united; and on the 10th of the month, just eleven days after the operation, I discharged my patient, as I hope, permanently cured.

"I am aware that it is not usual to treat hydrocele cases by excision of the sac, and then attempt to gain primary union; but in this climate the success of surgical operations is so very great, and the tendency to primary union so remarkable, that I felt justified in attempting the same in this case, as it was desirable to avoid all suppuration. There was very little inflammation following the operation, and, with the exception of some congestion and weight of the testicle (not more, however, than usually remains after an ordinary case of orchitis), I may pronounce my patient cured.

"I am pleased to report this case to the Society, not alone on account of its rarity and the interest which I believe it will afford, but because its results so fully sustain the views of Dr. Tyson as to its origin,—viz., 'a leakage of a lymphatic into the sac of the tunica vaginalis.'"

Dr. J. M. BARTON said he had been much interested in the preservation of this fluid in a specimen presented by him, and in the case of the specimen presented some time ago he had tried sulphite of sodium, carbolic acid, salicylic acid, and, finally, hydrate of chloral, with which he succeeded.

(To be continued.)

REVIEWS AND BOOK NOTICES.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE. Edited by Dr. H. VON ZIEMSEN. Vol. II. ACUTE INFECTIOUS DISEASES. By Prof. THOMAS, of Leipsic, Dr. CURSCHMANN, of Berlin, Dr. ZUELZER, of Berlin, Prof. HERTZ, of Amsterdam, and Prof. VON ZIEMSEN, of Munich. ALBERT H. BUCK, M.D., New York, editor of American edition.

The second volume of this great work bears out in every way the promise of its predecessor. The different subjects have been assigned to writers each possessing peculiar fitness for the allotted task, and, we are glad to add, not too old to give it careful thought and assiduous research; the latter is especially evident in the authorities arrayed under each subject, some of the articles fairly bristling with bibliographical lore.

The subjects varicella, measles, and rubeola are treated by Prof. Thomas, the translation being by Edward Wigglesworth, Jr., M.D., of Boston. Prof. Thomas finds it necessary to combat the view of the identity of varicella and variola which is still held by some authorities, notably Hebra of Vienna. Measles receives considerable attention, the subject of anomalies and complications being treated at some length. We are inclined to believe that the mortality is estimated at a somewhat lower rate than recent accounts from Fiji would support. Rubeola, rötheln, or German measles is a disease which has not hitherto, we believe, found place in any systematic treatise upon medicine published in this country;* nevertheless the affection does occur here not unfrequently, as Dr. I. Lewis Smith† has shown, and Dr. Thomas's lucid account of it will be read with interest.

The article on scarlatina is also from the pen of Prof. Thomas, the translation being by Edward Frankel,

* We must except Drs. Meigs and Pepper's work on Diseases of Children, which contains a full account of the affection.

† Archives of Dermatology, October, 1874.

M.D., and John C. Jay, Jr., M.D., of New York. It is quite a book of itself, covering some one hundred and fifty pages. Under the head of treatment, especial stress is laid upon warm and cold baths and inunction, baths being recommended even in commencing nephritis.

Dr. Curschmann contributes a somewhat more concise article on smallpox, translated by George H. Fox, M.D., of New York.

Dr. Zuelzer's contributions comprise erysipelas, miliary fever, translated by Jas. C. White, M.D., of Boston, and dengue, influenza, and hay-fever, translated by I. Haven Emerson, M.D., of New York. As regards the etiology of erysipelas, Zuelzer is strongly inclined to attribute to it a fungous or bacterial origin. His description of treatment, local and constitutional, presents the usual array of vaunted specifics. He himself prefers the expectant plan combined with a nourishing diet. In the more serious forms with high fever he advises the use of the mineral acids with quinine: cold baths are also recommended. Locally, Zuelzer suggests merely the use of powdered starch and cotton wadding, together with perfect rest. Occasionally the surface may be painted daily with collodion to which glycerin has been added in the proportion of one part to fifteen, in order to prevent cracking. It forms a good covering and exerts mild compression. Ice-bags are recommended in severe cases.

The articles on miliary fever, dengue, influenza, and hay-fever are necessarily somewhat brief. Under the head of treatment of hay-fever the forlorn announcement is made, "Treatment is still powerless against hay-fever."

Prof. Hertz treats at length of malarial diseases, going into the subject of their geographical distribution and etiology with considerable detail. This article will perhaps prove one of the most interesting in the volume to American practitioners, particularly in the South and West. Its translator is found appropriately in the Mississippi Valley, in the person of Edward W. Schauffler, M.D., of Kansas City.

Prof. Von Ziemssen himself concludes the volume with a contribution on epidemic cerebro-spinal meningitis, translated by A. Brayton Ball, M.D., of New York.

Looking at the volume in its entirety, we must testify to the agreeable and easy style in which the various contributions have been written, making the book exceedingly pleasant reading. Much credit is due in this respect to the ability of the translators, and especially to the pains-taking fidelity with which the editorial portion of the work has been accomplished.

Some complaint has been made of the cumbersome size of the volumes of this work; but, although the one before us would hardly be found suitable for the "Leisure Hour Series," the inconveniences of its bulk are compensated in our mind by the clear and open type, and the almost creamy richness of the paper upon which it has been printed.

A. V. H.

SELECTIONS.

VALENTI Y VIVO ON THE ANTAGONISM BETWEEN STRYCHNIA AND MONOBROMIDE OF CAMPHOR.—Dr. Valenti y Vivo has made a series of researches on the supposed antagonism between these two substances, and has arrived at the conclusion that monobromide of camphor may be considered as an antidote for strychnia. According to Dr. Valenti, the following conclusions are well established (*Siglo Medico*, April 18, 1875):

1. Twelve dogs, after taking a fatal dose of strychnia, were saved by the use of bromide of camphor. The

experiments were practised in a satisfactory manner, with crucial tests.

2. The tetanic convulsions produced by strychnia may be reduced in force and frequency by the use of bromide. The action of the antidote is rapid and sure.

3. The hyposthenic action of the bromide mitigates the reflex activity of the poison. The tonic convulsions are converted into clonic.

4. The physiological antagonism is comparatively limited. A strong dose of bromide of camphor is necessary to antagonize the effects of strychnia.

5. The bromide acts on the sympathetic nerve; this is demonstrated by the myosis and the cardiac paralysis which were observed after its administration.

6. After an overdose of bromide, the united effects of the poison and the antidote produce death by syncope; when death takes place during the strychnism and without the antidote, cardiac impulses are observed post mortem; when it takes place after and through the use of bromide, cardiac impulses are never observed.

7. The experiments show that it is preferable to introduce the bromide by gastric ingestion and in small and repeated doses. The subcutaneous method, employed in some experiments, has not given satisfactory results.

GLEANINGS FROM OUR EXCHANGES.

CROUP AND DIPHThERIA (*The St. Louis Medical and Surgical Journal*, June, 1875).—Dr. Edward Montgomery enumerates the following characteristics which prevent him from accepting the doctrine of the identity of croup and diphtheria:

Croup is mostly confined to infancy and childhood, while diphtheria may and does attack all ages. Croup is neither infectious nor contagious, whilst diphtheria is eminently so.

Croup generally comes on suddenly in the night, the patient having been apparently well on going to bed, whilst diphtheria is preceded by many hours of general *malaise*, with a gradual exacerbation of symptoms.

The course of croup is short,—often two days, and rarely exceeding four,—whilst diphtheria extends from seven to twenty days.

In croup there is no swelling of the throat or of the cervical glands, whilst both these phenomena are present in diphtheria.

In croup there is no fetor from the throat, in diphtheria there is a strong and disagreeable odor. In croup the false membrane is mostly confined to the larynx and trachea; in diphtheria it rapidly invests the whole mucous membrane of the throat, involving the air-passages and the nostrils, and often appearing in the œsophagus, anus, and vagina.

In croup the false membrane is lighter in color, not so thick, and when detached does not leave a deep eschar and does not form on wounds or abraded surfaces; in diphtheria the membrane is dense, dark-colored, when detached leaves a deep eschar which readily bleeds, and is apt to form on wounds or abraded surfaces.

In croup there is no dysphagia, and no fetid discharge from the throat and nostrils; in diphtheria swallowing is accompanied with great difficulty and pain, and a fetid exudation from the throat and nose is almost invariably present.

In croup there is seldom much albumen in the urine, and when present it is in the advanced stage of the disease; in diphtheria albuminous urine is the rule, and often quite extensive in the commencement of the malady.

Croup has rarely any sequel to be dreaded, whilst diphtheria is often followed by paralysis, loss of voice, dimness of vision, deafness, dysphagia, etc.

In croup there are not the severe constitutional symptoms, great prostration, and other signs of septic poisoning which so generally obtain in grave diphtheria.

In fully-developed membranous croup the majority of the cases are not affected by any medicines hitherto employed, whilst in diphtheria medical treatment can accomplish much good.

LARYNGEAL DISEASE IN RELATION TO PULMONARY PHTHISIS (*Transactions of Ninth Annual Meeting of the Medical Association of the State of Missouri*).—Dr. W. C. Glasgow reports the following interesting case as illustrative of the connection between the diseases of the throat occurring as a complication in pulmonary phthisis, and other manifestations of struma:

W. M., aged 16 years, seven years ago had a large strumous ulcer on the leg; this continued open three years; one year after healing of ulcer, another formed under the clavicle, which did not heal for two years; one year after healing, another formed on the forehead; several months after this had healed, he experienced trouble with his throat,—pain and difficulty of swallowing. When first seen, he was suffering from great dyspnoea and dysphagia,—the effort of swallowing causing great pain,—and the fluids, for he could swallow no solid food, were regurgitated through the nostrils. There was complete aphonia. A laryngoscopic examination showed complete destruction of the epiglottis to its base, great thickening of all the parts of the larynx, and œdema so great that the opening into the glottis presented a rounded form, not the usual oval presented by the cords. An examination of the lungs gave dulness over the left infraclavicular space, prolonged expiration, both inspiration and expiration of bronchial character, and numerous moist crackling râles; the right side anteriorly gave harsh respiratory murmur. He presented all the symptoms of pulmonary phthisis,—continued hectic, night-sweats, impaired digestion, and general bodily prostration, with loss of strength and weight.

Under local and constitutional treatment, the difficulty of swallowing ceased, respiration became free and natural, and all the local and constitutional symptoms disappeared except the aphonia, which remained unchanged. The larynx remained greatly thickened and distorted, but there was no impediment to respiration or deglutition. The respiratory sounds over the left lung assumed a broncho-vesicular character, and all signs of active irritation ceased. The patient regained strength and weight, and appears in good bodily health, with the exception of aphonia and a pustular eruption, which made its appearance several months after the active disease in the larynx had subsided, and which still continues, the pustules discharging a strumous pus.

EXTERNAL USE OF TURPENTINE IN THE TREATMENT OF TONSILLITIS.—In the *Leavenworth Medical Herald*, Dr. S. H. Roberts strongly recommends the use of turpentine externally in tonsillitis. He folds the flannel to four thicknesses, wrings it out in hot water, and pours oil of turpentine over a spot the size of a silver dollar. The flannel is then applied over the sub-parotid region, and the fomentation continued as long as it can be borne. After removal, a dry flannel is applied, and the same region rubbed with turpentine every two hours. This application is continued daily till resolution occurs. The doctor believes, from the evidence of his long experience, that thus applied early in the disease the oil of turpentine has almost a specific effect in tonsillitis. That its action is not simply that of an irritant he has proved by employing mustard, croton oil, tincture of iodine, etc., in the same class of cases. They always

failed to diminish the inflammation of tonsils, while the turpentine succeeded.—*New Remedies*, April, 1875.

MISCELLANY.

SOCIETY OF THE ALUMNI OF THE AUXILIARY DEPARTMENT OF MEDICINE OF THE UNIVERSITY OF PENNSYLVANIA.—The graduates of the Auxiliary Department of Medicine of the University of Pennsylvania who have received the degree of Doctor of Philosophy have organized an alumni association, and elected the following officers: President, Dr. Roland G. Curtin; Vice-President, Dr. De Forrest Willard; Corresponding Secretary, Dr. Edwin L. Evans; Recording Secretary, Dr. Charles K. Mills; Treasurer, Dr. John Guitéras; Executive Committee, Drs. George C. Laws, J. William White, Adolph W. Miller, George Kerr, Edward T. Bruen, John R. Partenheimer, James B. Walker, John R. Haynes, Robert Simpson, and Andrew Macfarlane.

The first annual meeting of the Society was held at the University on the afternoon of June 24, 1875. Resolutions were adopted instituting a "George B. Wood Prize" of fifty dollars, to be awarded to that graduate of the Auxiliary Department of Medicine who should pass the best examination and present the best thesis embodying original investigation.

ICE IN THE HOUSE.—The use of ice in small quantities frequently repeated is very general in many diseases, but it is generally found to be a difficulty to keep it from melting, especially in small blocks. Dr. Schwarz recommends, to obtain this result, that the ice should be put in a vessel covered with a plate, which vessel should be placed on a feather-bed and covered with a feather-pillow or cushion, feathers being very bad conductors of heat. Dr. Schwarz states that by this plan he has been able to keep six pounds of ice for eight days when the thermometer marked summer heat.

LADIES FOR LADIES.—Madame Brès, who last week read a thesis before the Paris Faculty of Medicine and obtained a doctor's degree, is reported to have been appointed physician to the Sultan's harem at Constantinople.

The number of Professor Huxley's students in Edinburgh University now amounts to upwards of three hundred and fifty.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 29, 1875, TO JULY 3, 1875, INCLUSIVE.

MIDDLETON, J. V. D., ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for an extension of two months. S. O. 118, Department of Dakota, June 24, 1875.

GIBSON, J. R., ASSISTANT-SURGEON.—Assigned to duty at Fort Fetterman, Wyoming Territory. S. O. 73, Department of the Platte, June 26, 1875.

HUBBARD, V. B., ASSISTANT-SURGEON.—Relieved from duty at Jackson Barracks, Louisiana, and assigned to duty, temporarily, as Medical Director of the Department. S. O. 120, Department of the Gulf, June 25, 1875.

BROOKE, JOHN, ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 130, A. G. O., June 30, 1875.

SATURDAY, JULY 17, 1875.

ORIGINAL COMMUNICATIONS.

PLACENTA PRÆVIA, WITH A CASE.

BY S. J. RADCLIFFE, M.D.,

Member of the American Medical Association, etc.

PLACENTA PRÆVIA is one of those accidents incident to puerperal women, that may rightly be dreaded by both practitioner and patient, since its very rarity prevents the ordinary practitioner from becoming familiar with it. The only obstetric horror that can compare with it is convulsions; and these, anæsthetics have, in some measure, robbed of their terror.

In regard to the relative frequency and mortality of mother and child in puerperal convulsions and placenta prævia, Hodge says in regard to the first that authors vary exceedingly. "Thus, while Velpeau reports their frequency as one in a thousand, Madame Lachapelle fixes it at one in two hundred. Dr. Churchill, in his elaborate tables, gives the average of French and English practice as one in six hundred and nineteen nearly." He says, "Merriman states that out of fifty-one births, thirty-four were still-born,—about sixty-six per cent."

The second occurs once in about five hundred cases. Dr. Hodge quotes Dr. Frank's Prize Essay and valuable tables, published in 1855 in the *Trans. Am. Med. Assoc.*, that deaths from unavoidable hemorrhage prior to the full period were twenty-four per cent., while the deaths among the children were one hundred and sixty-six in two hundred and sixty-two; being a mortality of sixty-three and one-half per cent. Barnes says, "I had occasion to review my experience of the terminations of sixty-nine cases of placenta prævia. The deaths were 6,—i.e., one in $11\frac{1}{2}$, a proportion much smaller than that usually given in statistical tables."

With this view of the matter, then, this class of cases cannot be put off to a more convenient season. What must be done must be done quickly; promptness in action and in relief must be the uppermost thought, and, with this, a comprehensive view of the entire situation before you.

The main object to be kept constantly in mind is to staunch the hemorrhage, as the case may be, and thus to save life,—to save the life of the mother at least first, and secondly of the child, if viable, if possible.

Whatever treatment may be decided upon ought to be the right one for the emergency, for when once done it is done forever; it cannot be undone. But in the greatest emergency, and when hope of saving life may have almost fled, an attempt ought still to be made to do something towards it. I remember seeing a case at term with an intelligent physician of this city, several years since, where forced delivery was practised by turning under the use of ether, after means had been used to dilate the os and to bring on labor, without success. Though the case seemed to be a desperate

one, the means seemed to be happily well adapted to the condition of things, and though there was considerable shock and great loss of blood, the woman rallied for the time, but died of pyæmia, or septicæmia, probably, on the twenty-first day after delivery. The child I resuscitated after considerable effort, and it is now living, a hearty, healthy child of about five years.

It appears to be the prevalent opinion at the present day that when there is imminent and immediate danger of loss of life, excessive hemorrhage, shock, and exhaustion of the vital powers, delivery should be attempted at once, without any regard to the general condition of the patient; and this, too, even at the expense of the child, unless it is clearly proven that it may be saved; though some, as Simpson, consider it ought hardly to influence the treatment.

If, then, we have a case of placenta prævia clearly made out by examination, no matter at what period of gestation it may be presented to us after the fifth month, with profuse hemorrhage, perhaps coming in gushes, or in a continuous stream, with much shock of the nervous system and failing of the vital powers, our duty is clearly to attempt to deliver without any delay, and banish the thought to protract gestation with a view of having a more favorable result; and in this event one of two procedures will occupy the attention: either to try to force the hand through the undilated cervix, seize the feet, turn, and forcibly deliver,—*accouchement forcé* of the older writers,—and then remove the secundines as rapidly as possible; or to introduce one or two fingers through the os and into the uterus as far as possible, sweep them rapidly around the cervical zone of Barnes, separating the placenta, as far as the fingers reach, from the uterus, as first recommended by Simpson, then rupture the membranes, if in no other way, directly through the placenta, bring on labor by ergot, the binder, or the tampon, and leave the case, under surveillance, to nature.

Those who believe, with Churchill, that "the flooding is the necessary consequence of the dilatation of the os uteri, by which the connection between the placenta and the uterus is separated, and the more labor advances the greater the disruption and the more excessive the hemorrhage," will adhere, perhaps, to the former plan; while those who admit that the detachment of the placenta arises from an excessive rate of growth of placenta over that of the cervix will more readily rely upon the latter.

The former operative procedure is considered a very harsh and cruel one, greatly endangering the life of the mother, not only immediately by forcible dilatation, by rupture or laceration of the soft parts and consequent hemorrhage, but more remotely by septic or pyæmic poisoning, and not necessarily adding to the chances of the safety of the child; while the separation of the placenta within a given circle is considered more practicable, more easily accomplished, and gives better results for the mother and some chance for the child, as the hemorrhage is almost certainly arrested. Barnes says, "There

are two conditions present in flooding from placenta prævia. The *first, an immature uterus*. Flooding frequently occurs before the term of gestation is complete. The uterus is therefore taken by surprise before its tissue is developed, before it has acquired its normal contractile power. Besides this, the uterine neck is ill adapted to expand. The *second is the loss of blood* itself, impairing the vital power, causing shock and prostration. The several or the joint production of these conditions is a powerless labor, the absence of contraction. Hence the continuance of hemorrhage. We feel we cannot depend upon contractile force when all force is ebbing away with the blood; we are compelled to act, to assist nature in her extremity."

Considering the force of these two propositions as factors in the case,—viz., first, immature uterus, and, secondly, loss of blood, as present in placenta prævia,—we cannot be slow in appreciating also the force of the possible effects of treatment.

But, without attempting a discussion of the subject of placenta prævia in all its entirety, the following case will somewhat illustrate the mode of treatment in the management of placenta prævia more elaborately elucidated by Barnes in his work on "Placenta Prævia," and in his "Obstetric Operations."

CASE.

I was called, November 17, 1874, to visit Mrs. T. F., a plump, healthy woman, of Irish descent, about 32 years of age, mother of five children, and who had had remarkably easy times in all her labors. She stated that she had suffered from uterine hemorrhage for several days,—part of the time it had been very profuse,—and that, as she supposed herself pregnant about two months, she thought it possible she had miscarried. As I had no positive means of ascertaining whether or not she had aborted, and supposed it possible, I prescribed for her, enjoining rest and quiet, and after a few days the hemorrhage ceased. I saw her again in February last, while attending one of her children. She informed me she had discovered she had not miscarried, but she had had some flow each month at about the menstrual period, which she thought strange. Without making an examination, I still supposed it might yet be attempts at miscarriage, and insisted strongly upon the recumbent position and quiet at those times. I was called to visit her again, March 13, in haste, and found she had had a sudden, profuse hemorrhage, losing, possibly, between thirty and forty ounces of blood. She was taken on the sidewalk before her door, and, before she could be got up to her chamber, saturated her clothes and marked the floor on her way up the steps. I found about twenty ounces in the chamber-vessel, which she passed in it after getting up-stairs. I was surprised to find her in such good spirits and in such good condition after such a drain upon her. It really made very little impression upon her pulse, and she was not at all depressed by it. I made a digital examination then for the first time, and discovered the whole source of the trouble. The placenta was planted directly over the cervix, and nothing but

placental tissue could be felt, the os being open as much as is commonly observed in multiparæ at six months. I immediately notified her friends of her condition, explained to them the cause of her flooding and the danger she was constantly in from the same cause; that she must be watched, and I sent for on the first recurrence of the hemorrhage. The flow ceased on the 14th. I saw her twice on the 14th, and once each day till the 17th. She moved about her room and the adjoining one again, and, though a little pale, was quite strong and active.

I was awakened half an hour after midnight of the 18th, and was informed she had had a sudden and profuse hemorrhage while in bed, and was still flooding. I hastened to her, and found her in a state of great consternation and alarm, with a nervous chill, and having a great desire to have done for her what I had told her I might have to do,—that is, deliver her by artificial means. I saw her three times on the 19th, and on the 20th the flooding ceased. Up to this time the treatment had been only palliative or expectant, as I thought I had not arrived at the period when life was really in jeopardy, and feeling I had more active means as a *dernier ressort*, and feeling also that either horn of the dilemma was perilous,—the flooding or the induced labor and delivery,—I deferred further operation, hoping still gestation might go on to a time when delivery would be more easily and safely accomplished. But this, it will be seen, was futile.

On the night of the 21st the flooding came on again violently. She bled profusely all night, blanching her, reducing her to the lowest ebb compatible with life, placing her in imminent peril. On the morning of the 22d, finding all hopes dissipated of prolonging gestation to a period nearer her term, I concluded immediate delivery was the only means offered, if any, to save the patient's life. On examination I found the os and cervix rigid and unyielding, and could scarcely more than introduce one finger or two with force, and I could feel the warm blood trickling fast by. She was pale, had even a greenish, chlorotic hue of countenance, pinched features, sunken eyes, a shiver once in a while coming over her; surface cool, feet cold, pulse very faint and slow, scarcely perceptible at the wrist, and she was on the very border of death.

Desiring consultation, I suggested Dr. I. H. Thompson as most accessible, who was sent for to meet me. In the mean time I placed her in position across the bed with the parts towards the light, and attempted to introduce Barnes's dilator. Dr. Thompson arriving to my aid, he suggested immediate forced delivery by turning. I introduced my hand into the vagina, and attempted to force my fingers through the cervix, Dr. Thompson holding well down the uterine globe, but I found it tiresome, and utterly impossible in the then condition of the parts. I could only get in two fingers, and while I had them in, forcing them as far as I could reach I swept them around between the placenta and the uterine walls, completely detaching the former within that circuit. While I was manipulating, Dr. T. whispered to me that the pulse had gone at the wrist. As no time could be lost, requesting Dr. Thompson

to relieve me and change positions, he found it also impossible, without risk of injury, to introduce the hand for the purpose of delivery, but finding the bleeding had entirely ceased, I requested him to rupture the membranes *through the placenta* with a quill, which I had prepared for him, which was readily and promptly performed. Only the amniotic fluid now flowing, we agreed to plug the vagina with raw cotton, which was soon done, completely packing it in as tightly as could be, and that there might be no possibility of its escape we applied the T-bandage, and over the uterus also a narrow binder. With a few doses of brandy, the patient now rallied somewhat; the pulse, though feeble, could be felt at the wrist. We directed the brandy to be continued at short intervals, and a teaspoonful of Squibb's fluid extract of ergot to be given every half-hour; and we left her, to meet again at 2 P.M.

2 P.M.—There had been no bleeding since our last visit; she was comparatively comfortable, and had taken a cup of tea and a little toast. Her breathing was rather sighing and irregular, pulse feeble, 110, surface cool; said nothing, made no complaints, except that she had some pain in left side; plug saturated with dirty watery fluid; continued brandy and ergot, with little beef-tea in intervals. We saw her again at 7½ P.M.; she was more comfortable than when last seen, talked better and stronger, pulse more volume, some reaction and more warmth of surface, no hemorrhage; some uterine pain at long intervals, indicating contraction; very anxious about herself; said she felt true labor-pains, and begged me not to leave her. Dr. Thompson thought we could safely leave her till morning, as there was no urgency, no severe pain, or uterine contraction, and no hemorrhage; and there would be danger of recurrence of bleeding if the plug was removed, and she would be stronger and better able to undergo any further operation if deferred until morning. As she desired I should stay with her, I remained. At 8½ P.M. the pains became more frequent and expulsive, with some effort at displacement of the plug; they continued to grow stronger, quicker, and more effective; and at 9 P.M., finding the plug starting outwards, I sat by her and with forceps removed the plug of cotton, piece by piece, until all was removed; and then introducing my hand into the vagina, I found the placenta emerging into the passage; I seized and removed it; and as the os was now well dilated, I seized one foot and then the other, and, simply aiding the expulsive efforts of the uterus, delivered a six-months' foetus at about 9.10 P.M., without accident of any kind,—with scarcely a drop of blood.

The foetus had been dead evidently some hours, though she said she thought she felt it in the morning, just previous to the attempt to introduce the hand. The placenta was dark, congested, and not firm in feeling. The uterus contracted well. The patient felt now much relieved in mind, and rallied astonishingly at once. Her mattress was moved to the ordinary position, and she was made comfortable by removing her wet clothes. She had taken in about twelve hours an ounce and a half of fluid ex-

tract of ergot, without injurious effect. It sickened her towards the last, causing it to be rejected.

Her case went on now hopefully for several days, though the vital powers were greatly reduced, and the functions of the heart and lungs and the general circulation were exceedingly enfeebled. The pulse had not varied much from the range of 100 to 108, nor the temperature much from 100°. The vaginal discharges were watery, of a dirty muddy color, without much odor.

On the 27th, I noticed the discharges were quite offensive and more profuse, and had changed to a thin, yellowish, purulent character. A hectic flush lighted up her cheeks; there was more or less restlessness, and some hebetude, varied by drowsiness; and I began to feel the case might be lost at last by septicæmia.

I ordered ten grains of sulphite of sodium in elixir of calisaya every four hours; a vaginal wash of salicylic acid, twenty grains to the pint of hot water, used three times daily; and five grains of quinia each morning daily, with continuation of the brandy and beef-tea.

I had no further trouble after this. The condition of the patient gradually improved in every respect until the 3d of April, when the pulse was down to 90, with more volume and regularity; the temperature was normal, and symptoms of septic poisoning had entirely disappeared. All medicine was now discontinued except twenty drops of muriated tincture of iron three times a day, and beef-tea and brandy at longer intervals than before.

I continued in attendance until the 10th of April, when she was able to sit up in bed, had been on the floor the day before, relished her food, had improved in color and general appearance, and was altogether cheerful and happy over the result; four grains of quinia once daily, with twenty drops of muriated tincture of iron three times daily, were directed to be continued for awhile longer as a general tonic, with special directions to have a watchful care over herself, and particularly to see that she did not move about too soon.

On the 30th of April, I was surprised to have a call from her. She had walked several squares to see me, to show me how well she was. The consequence was she was "unwell" the next day, which lasted four days.

She called again on the 31st of May, and stated since that time she had no further disturbance; she looked well, had regained much of her flesh, and had a good rosy color.

NO. 1211 F St., N.W., WASHINGTON.

QUININE IN PERTUSSIS.

BY EDWARD T. BRUEN, M.D.

I WOULD like to offer to the readers of the *Times* a few practical observations upon the use of quinine in whooping-cough, which, although trite to some, may perhaps cause the successful use of the remedy by many others.

I had prepared a detailed account of seven cases I have treated with this drug in dispensary and

private practice, but, as they seemed repetitions of each other, I shall simply state the facts drawn from my clinical study.

In many cases, if the drug is used continuously, it either signally fails to relieve or else it affords but slight benefit. The proper method is to administer it by rapidly-increased doses for a period not longer than five days, after which it should be stopped, and after an interval, if necessary, recommended.

If at any time during the twenty-four hours the paroxysms are especially violent, it is a good plan to administer the quinine at such intervals that a full dose shall be given one hour or two before the spell is expected. I have known of cases which have been most benefited when the quinine has been given in large amount in two doses. This, I have been told, has been the best means when the spells were very violent during the night. I have never used the drug in this way myself. The amount of quinine given in pertussis seems often limited by the fears of the medical attendant. I have found that to accomplish good the medicine must be pushed to a quantity equal to a full anti-periodic adult dose. To a child under three years old at least ten grains should be given in twenty-four hours; to one of twelve years, from sixteen to twenty grains in the same time. It is only by using these full doses that good can be accomplished or cures made. A word concerning what should be expected of the drug.

In many instances I have seen it cut down immediately the number of the paroxysms from forty or fifty daily, as registered by pin-holes in a card, to only eight or ten; the case afterwards rapidly recovering similarly to those which have run their full course. In more rare cases it is positively curative, but the great relief afforded is amply sufficient to make us employ it when other means are so constantly ineffectual.

In my hands it did not usually moderate the violence of the paroxysms: this effect is generally seen to occur gradually after the spells have been reduced. I have seen only a few cases where unfavorable symptoms appeared during the treatment by quinine; one child of fourteen months, who had taken ten grains of quinine for two days, manifested symptoms of congestion of the brain, which yielded promptly to treatment, the disease being also cured. In one or two other cases a little drowsiness and headache were the only unfavorable symptoms, but these effects came on gradually, and I believe there is no danger in using quinine freely as I have recommended, provided we watch our patients with ordinary care.

WATER IN FEVERS.—Dr. Tauszky says (*New York Medical Journal*, July, 1875) that it can be put down as a law that the reheating of the body takes place the quicker, the colder is the heat-depriving medium applied, the more force, such as friction, movement of the body, or of the water, is used. If we desire to retard the reheating of the body, the applications must be made at longer or shorter intervals, and last for a longer or shorter period of time, proportionate to the degree of fever.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. H. C. WOOD, M.D.

Reported by CHARLES K. MILLS, M.D., Chief of Clinic.

SCIATICA AND NEURALGIA TREATED BY THE CONSTANT CURRENT.

SCIATICA.

P. M., æt. 56, married, came to the clinic February 17, 1875. His life had been chiefly one of hard work and exposure. Eight years before, he first had an attack of sciatic neuralgia, which lasted about a year. Now and then since, especially in cold weather, he had had pain, sometimes violent, along the line of the sciatic. For five months he had seldom been free from pain.

When first seen, he walked with his body much bent, using a cane. A slight jar would cause a violent paroxysm of pain. The right leg grew tired with slight exertion. Pressure over the sciatic at almost any point would cause pain, but three points of peculiar tenderness—points *dououreux*—could be readily made out: the first about the sacro-iliac junction; the second, between the great trochanter and tuber ischii; and the third, about the head of the fibula.

It was determined to try the efficacy of a pure galvanic treatment. The current used was derived from Siemens-Halske cells. Twenty sittings were given, covering six weeks, and each lasting from ten to fifteen minutes. The current was not interrupted, and was of just sufficient strength to allow the patient to say that he felt it distinctly, eight applications being made with five cells, seven with ten, and five with fifteen. The two poles were generally placed over the sciatic, at points varying from a few inches to two feet apart, but sometimes the positive electrode was applied over the lower dorsal region of the spine, and the negative along the line of the nerve.

The patient improved from the first, notwithstanding unpropitious weather. His treatment was commenced February 22, with five cells. He reported and was treated with five cells February 23, 24, 25, 26, and 27, constantly improving in sleep, strength, gait, general facility of movement, and amount of pain. He experienced relief after each sitting. From February 27 to March 4, owing to the weather, he did not report, his condition remaining about the same. March 4 and 5, five cells were used with benefit. He did not return again until the 10th. He got chilled on the 5th, and suffered great pain on the 6th, 7th, 8th, and 9th; but was not as bad on any of these days as he had been before coming under treatment. From March 10 to April 7, when he ceased to attend, he was treated twelve times, with either ten or fifteen cells. His leg continued steadily to improve, notwithstanding the severe and changeable weather, the long distance—about six miles—which he had to come, and the fact that several days sometimes elapsed between the applications. He complained of some pain in the side and back occasionally, but the sciatica appeared to be cured. He could bear his whole weight on the right leg, and could walk erect without a cane. The limb felt stronger than it had done for years. It could be handled with impunity, without causing pain. The points *dououreux* had vanished; not a drop of medicine was given, and no liniments or other external applications were used.

If this patient could have been admitted to the hospital, and the sittings have been more frequently repeated, with rest in bed as an adjunct to the galvanic

treatment, he could probably have been discharged, well, in from two to three weeks.

An important point in the history of this case, as bearing upon the question of the efficacy of galvanism to alleviate pain, is the fact that after every application the patient experienced marked, and, in some instances, signal relief.

This case was under observation during the latter part of February, the whole of March, and the first week of April, embracing a period when the weather was variable and severe; and some notes were taken upon the influence of the state of the atmosphere upon pain. The patient could foretell a storm by the painful sensations in his leg. The pain was always most violent when a storm, either of rain, hail, or snow, was coming on. After the storm was fully established, it would sometimes abate remarkably. From personal observation of the weather, and from consultation of the records of the Signal Service, the pain seemed to be greatest on days when the barometer ranged about 30; when the thermometer stood between 25° and 30°; before and during storms; when the wind was changing to the east, and when east winds prevailed; and when the air was heavily charged with moisture. The observations and comparisons, however, were not sufficiently extensive and systematic to allow any positive general conclusions to be drawn.

NEURALGIA.

E. E., æt. 45, married, had enjoyed good health until four years before coming for treatment, when she began to suffer from neuralgia of the left side of the face and head. She had had attacks every week or two since, which recently had been getting worse. The pain was severe, and most marked over the left brow. During the paroxysms of pain she could scarcely see, and her eyes were intolerant of light. A tender spot, corresponding to one of Valleix's points *douleureux*, was found just above the centre of the left eyebrow. Her appetite was poor, but her general health was otherwise pretty good.

On the day of coming under observation, the use of a galvanic current of five cells was commenced, placing the positive pole in front of or below the ear, and the negative over the supra-orbital nerve. She came twice a week to the clinic, and received thirteen applications, when she was discharged, cured.

She only had one attack while under treatment. By request, she reported one month after her discharge, up to which time she had had no recurrence of the neuralgia. No medicine was employed.

SERVICE OF D. HAYES AGNEW, M.D.

Reported by WM. M. MASTIN, M.D., Resident.

RUPTURE OF THE ABDOMINAL WALLS, WITH BARTON'S FRACTURE OF THE RADIUS, AND OTHER INJURIES, FROM A FALL—DEATH—AUTOPSY.

J. K. S., 76 years of age, painter by occupation, a native and resident of Philadelphia, was received into the hospital June 15, 1875, in the following condition: About an hour before admission, while working at his trade, he fell to the ground from the second-story window of a dwelling-house, a distance of thirty feet. The whole force of the fall was received on the left hip and side and palm of the right hand. The man was very much shocked, and examination showed extensive contusion of the soft parts of left buttock and lumbar region, with comminuted fracture of crest of ilium, fracture of two lower ribs, and fracture of inferior third of right radius. A tumor, the size of a foetal head, occupied the left lower part of the abdomen on line with crest of ilium. This was elastic and compressible, with thin walls, dull on percussion, and communicated to

the finger the impression of its containing fluid. The position of the left leg, with a slight degree of shortening, suggested fracture of the neck of femur, but the injury to buttock and pelvis was so extensive as to mask all other symptoms, thus preventing a positive diagnosis. The fracture of the radius was diagnosed as Colles' fracture, with some comminution. Considerable difficulty was experienced in effecting reduction.

The morning following, the man was found to be some little better; reaction not established, but hopes were entertained of his recovery. There were no symptoms of internal injury, and the abdominal tumor was resonant and gurgling. The man complained of pain only in the arm, feeling no inconvenience from injury to side. He took food readily. Later in the day he showed evidences of sinking, and died that evening from shock and exhaustion.

Autopsy.—Body examined seventeen hours after death: abdomen distended and tympanitic. The tumor was first inspected, and found to be due to a protrusion of the intestine through a rent in the walls of abdomen. The tear in peritoneum was three and a half inches in length and parallel with the axis of body; that in transversalis and internal oblique muscles was across the direction of their fibres, whilst that of external oblique was in the line of and a mere separation of its fibres, so that the abdominal walls were ruptured in two directions: first, a perpendicular rent of peritoneum, transversalis, and internal oblique muscles, and second, an oblique of external oblique muscle. The integument remained intact, but was with the fascia dissected up from the muscles to two and a half inches on either side of the rupture, thus forming a large sac which was filled with fully three feet of the small intestine. A small knuckle of the protruded portion of the gut had insinuated itself into a pocket between the two oblique muscles, and was completely strangulated, being in a state of gangrene. One of the branches of mesenteric artery had given way, as shown by an effused clot in abdominal cavity. No evidence of peritonitis existed, except a slight localized injection of the visceral peritoneum. The fracture of the innominate bone was seen to involve the anterior superior spinous process, and a large portion of the superior part of the crest. The ribs were broken at their angles. There was no fracture of femur, but a partial luxation upwards of that bone; the capsular ligament being torn, the head of the bone rested on the upper margin of acetabulum. By far the most interesting feature of the post-mortem was the fracture of the radius. This was a true Barton's fracture,—a fracture extending into the joint. The bone was broken transversely an inch above the articulating surface, with an oblique fracture extending some two and a half inches up the shaft, splitting off a large piece of the shaft, which was driven down behind the lower fragment, its end resting against the ulna. A longitudinal fracture passed through the middle of the lower fragment into the joint, dividing the articulating surface into two portions. Opposite the transverse fracture several spiculæ were lying loose in the connective tissue. There was no impaction, the difficulty in reduction arising from the displacement downwards of the split-off portion of the shaft.

VERATRUM VIRIDE IN EPILEPSY (*The Cincinnati Lancet and Observer*, July, 1875).—Dr. E. E. Riopel reports the case of a boy, æt. 6, who had severe epileptic convulsions, recurring frequently. Veratrum viride was given, commencing with one drop, and increasing every half-hour, until ten drops were taken. It was then given every hour, and continued for two days. The result was an entire cessation of the convulsions, and apparent recovery.

TRANSLATIONS.

GRAVE SCROFULIDES OF THE BUCCO-PHARYNGEAL MUCOUS MEMBRANE.—According to Dr. G. Homolle (*Thèse de Paris*, 1875, *Bull. Gén. de Thérap.*, No. 10), lupus of the face is accompanied in one case out of five with lesions of the bucco-pharyngeal mucous membrane, and these parts should always be examined when facial lupus exists. These lesions may be derived from continuity in the region of the commissures of the lips or the nasal fossæ, or more frequently may occur in the mouth or throat without direct propagation. They may take the erythematous, ulcerative, tubercular, hypertrophic, or canceroid form, the seat of the lesion having a marked influence upon the type which the disease assumes. Analogous affections may be primarily developed upon the mucous membrane of the palate, the isthmus, or the pharynx. They show themselves under two principal forms: lupus of the throat (progressive erosion) and ulcerating scrofulide (perforating ulcer). The latter coincides in certain young subjects with certain lesions which have been attributed to hereditary syphilis,—notched teeth, interstitial keratitis, etc. These primitive scrofulides of the throat are usually affections of childhood. Their favorite seat is the velum palati, and after that the posterior wall of the pharynx; they scarcely ever appear on the tonsils. The disease is rarely propagated to the epiglottis, and still more rarely to the larynx.

The grave scrofulous anginas are observed in manifestly strumous subjects. Tardy hereditary syphilis is perhaps one of the causes of their appearance. The diagnosis is always difficult. Syphilis must be constantly borne in mind, and a very careful examination of both patient and history should be made before pronouncing an opinion. Lupus of the throat, with progressive erosion and posterior adhesions of the hinder half-arches to the vault of the pharynx, is more easily distinguished than ulcerous scrofulides from other forms of chronic angina. The treatment is anti-strumous, with local cauterizations. X.

THE ELASTIC LIGATURE IN SPINA-BIFIDA.—At a recent meeting of the Société de Chirurgie, reported in the *Bull. Gén. de Thérap.*, No. 10, 1875, the reading of a case of spina-bifida occurring in a child three years old, operated on by elastic ligature and cured, became the subject of some discussion. Another case was cited in which the operation was followed by convulsions and the ligature had to be withdrawn.

M. Blot, who spoke on the subject, said that he had not entire confidence in the procedure. Nervous filaments, he remarked, were often present in these tumors, and even expansion of the cord; it is not therefore always prudent to interfere. Besides, he had found that these tumors decrease in time, and often disappear entirely at last. In the course of the discussion on the indications for operation, M. Despres said that when the tumor is not reducible, an operation may be performed without inconvenience. When, however, there is a large communication between the tumor and the spinal envelopes, it is necessary to abstain from all intervention. X.

ELEPHANTIASIS SCLERODERMA.—M. Vidal read notes of the following case before the Société des Hôpitaux, at a recent meeting:

The patient was a man thirty-seven years of age, of fine constitution, and who had always enjoyed good health. Two years previously he had suffered from sudden suppression of profuse perspiration, and subsequently from chilliness of the extremities; then the skin in the region of the eyebrows became red and indurated for some hours, but returned to the normal con-

dition. Afterwards erythematous elevations followed, which gradually invaded the arms, the fore-arms, the thighs, the scrotum; then violet spots, "varicosities" of the skin, a kind of local asphyxia, some superficial eschars, a marked condition of pityriasis. The skin is at present reddened, and in the neighborhood of the neck and on the back of the head a considerable thickening of the derm is perceptible, forming more or less isolated tumors.—*Bull. Gén. de Thérap.*, No. 10, 1875. X.

DOUBLE LIGATURE OF THE FEMORAL ARTERY.—A young man received an oblique wound of the superior third of the anterior external face of the right leg. By mistake only a simple dressing was applied, and five days later a pulsating tumor was observed extending to the lower third of the leg. Continued pressure failing to give relief after some days, Professor Landi ligated the femoral below the canal of the adductors. The operation was difficult, on account of the thick layer of fat. The aneurismal tumor ceased to beat immediately after the ligature. The ligature was removed in six days; but on the eighth day hemorrhage from the upper portion of the ligated artery took place, possibly on account of purulent infiltration in the sheath of the artery. The femoral was again ligated in Scarpa's triangle, and complete recovery, with perfect use of the limb, was the result.—*Bull. Gén. de Thérap.*, No. 10, 1875; from *Raccogliatore Medico*, January, 1875. X.

SUPPRESSION OF URINE FOR EIGHT DAYS WITHOUT URÆMIC SYMPTOMS.—Pourmadre (*Deutsche Zeitschr. f. Prakt. Med.*, May 29; from *Giornale Venet. di Sci. Med.*) gives the following case. A man, fifty years of age, complained that without any assignable reason he had been unable to urinate for the past twenty-four hours. On examination he was found to be suffering from serous diarrhœa with rheumatism, and he stated that for some time previously his urine had been reddish, cloudy, and thick with sediment. Rest, baths, and linseed poultices failed to relieve the anuria or the diarrhœa, although there was neither pain in the kidneys, quickening of pulse, nor increase of temperature. A catheter introduced into the bladder brought away only a few drops of urine. In the course of the next five days the abdomen became distended, and there was some inclination to vomit. On the sixth day there was meteorism, a small pulse, flushed face, some delirium and sopor, some appearance of blood with the diarrhœa. On the seventh day the meteorism and diarrhœa increased. An enema containing ether was ordered, together with a bath of two hours' duration. Soon after, a clot of blood with a few small calculi came from the urethra, a considerable amount of blood followed, and the suppression of urine was over. It is probable that the presence of the calculi in the urinary passages may have brought on cramp and anuria, while the urinary secretion was removed by the concomitant diarrhœa. X.

MERCURY IN THE MILK OF WOMEN DURING THE "INUNCTION CURE."—Kahler (*Deutsches Zeitschr. f. Prakt. Med.*; from *Rundschau*, 1875, s. 260) made examinations of the milk of three nursing women by electrolytic chemical analysis, any mercury contained in the milk being deposited upon a little gold electrode. The amalgam thus obtained was heated in a glass tube, thus volatilizing any mercury present. The latter was then converted into the iodide, giving a very striking reaction. Inunction of mercury in nursing women, practised so thoroughly as to cure any syphilitic manifestation which was present, yet failed to give a mercurial reaction to the milk. That some influence was at work was shown in certain cases in which syphilitic manifestations in the infant were cured even while no mercury could be found in the mother's milk. X.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 17, 1875.

EDITORIAL.

SOME WISE MEN OF GOTHAM.

QUACKERY in electricity is as much quackery as is quackery in patent medicines, and it seems to us that physicians should be just as careful in allowing their names to be associated with the one form of rascality as with the other. Paoli's electro-voltaic belt is probably as useless a piece of household furniture as any head of a family could invest his money in: patented in Washington, made in New York, it is self-puffed throughout the universe, literature, both secular and religious, from *Belgravia* to *John Wesley's Journal*, being laid under contribution to it. To show the real scope of this discovery, we give the following extract from a pamphlet very freely circulated by the company:

"With this end in view, all drugs should be discarded, and a more rational view of nature's laws observed. Drug medicines too often injure the system, arrest the digestion, and cause a simple acute disease to resolve itself in a complicated chronic one, often incurable by any method. In fact, drugs do much more injury than good. Still it must be acknowledged that, in some cases, drugs do effect a change in the secretory and circulatory processes, and thus assist nature in recovery; but it is only the one who has a strong vitality that derives benefit—the debilitated are always injured.

"We say without fear of contradiction, that every disease depending upon a debilitated condition of the vital forces, can be promptly and permanently cured by electricity, if properly applied. Life is supported wholly by electrical currents, and diseases are cured by the supporter of life; they are cured by electricity when every other means have failed.

"Paoli's wonderful discovery has now been endorsed and recommended by literary and scientific men of the highest rank; by the most eminent medical professors in Europe and America, who testify that Paoli's invention is the most effectual remedial agent ever discovered, and that nothing in the annals of science or medicine has ever approached it in its remarkable powers over the human system, and in the cure of disease."

Judge of our surprise, reader, when on continuing the perusal of this pamphlet we came upon a series of commendatory testimonials of "some of the most eminent physicians and professors of the city of New York, the originals of which can be seen at our office." The letters are really from men of position, interlarded with those from physicians, to speak mildly, not so reputable, and with those giving accounts of marvellous cures worked by these miraculous belts.

We refrain from mentioning any names, because we do not suppose these gentlemen gave these letters with a knowledge of the use to be made of them. We well remember the aid Swaim's Panacea received in a similar way in this city. The moral we desire to point is—Give no testimonials.

MEASLES AT THE ANTIPODES.

AN extraordinarily severe epidemic of this usually mild exanthem has during the last two years swept off a very appreciable percentage of the population of various places in the Southern hemisphere. During six months of 1873-74 it caused in the Mauritius Islands more than two thousand deaths, men, women, and children being embraced in the death-roll. In the summer of 1874 the disease was introduced into South Australia, whence it spread rapidly, appearing later in the year in Victoria and New South Wales, and the present spring reaching the Fiji Islands. In the latter locality the results are said to parallel those of the plague in Mediæval Europe; all ages stricken down, and the whole population pervaded with a frightful panic, so that no one ministers to the sick, and even the dead are left unburied. It is very probable that the accounts are exaggerated; but the general fact of the enormous mortality seems well established. In a people new to civilization, epidemics of civilization when they appear affect every one, because every one is equally susceptible, none being protected by previous attacks. The great mortality is no doubt in part due to neglect of all sanitary laws, to habitual filth, to no care or improper care of the sick, and various similar causes. In Melbourne sanitary neglect

was plainly very efficient in producing the great mortality. The epidemic occurred during the hot season, when the scanty water-supply was especially contaminated. To show the general recklessness, it is stated that one contractor was in the habit of dumping his nightly gathering of night-soil into the river whence the water was drawn, and that the economical city fathers used the public parks as depositories of human excrement.

In the case of the Fiji Islands, other causes are undoubtedly at work in producing the great mortality, which is said to have reached fifty thousand (?). It appears to be a general law that the diseases of civilization act with a frightful violence upon new, savage races. Thus, whole villages of our Indians have been swept away—actually exterminated—almost in a fortnight by smallpox. In civilized communities it is probable that there is handed down from father to son a trace of the acquired immunity against the attacks of these exanthematous diseases, so that every one is, at birth, at least so far protected that the violence of the attack is averted. Among savages the disease finds no such limitation by heredity. To borrow the language of the evolutionists, partial immunity from various exanthemata is, in the European, an acquired specific character which is wanting in the savage. Hence, according to the law of the survival of the fittest, the savage races must disappear unless, before extermination, they can acquire the disease-resisting powers of the white man.

WE desire to call attention to the Ophthalmological Congress, the scope of which is explained in the appended extract. We are glad that there is one Centennial congress not to meet in Philadelphia, and have full faith that our New York confrères will do all that can be done to make the Congress a success.

"The International Congress of Ophthalmology will meet in New York City on Tuesday, September 12, 1876, at twelve o'clock noon. The following extracts from the rules of the Congress will give an idea of the general character of the Society, and of the terms of membership:

"1. The object of the International Periodic Congress of Ophthalmology is to promote ophthalmological science, and to serve as a centre to those who cultivate it. It will entertain no discussion foreign to this object.

"2. The number of members is unlimited.

"3. Every member must be either a doctor of medicine, or of surgery, or of science, or possess some other equivalent degree, or be distinguished for his scientific knowledge.

"4. Candidates for admission into the Society shall be admitted on presentation of their diploma or of their scientific title, unless ten members demand a ballot.

"5. The sessions of the Society shall take place every fourth year, and be limited to ten days.

"11. The Society gives no diploma. Before the opening of each session a card available for admission to all the meetings, and signed by the President and Secretary, shall be given to each member on payment of his subscription (fixed at \$2), and upon signature of his name on the register of those attending the meeting.

"Among the members of this Congress are such men as Arlt and Stellwag, of Vienna; Giraud-Teulon, Javal, and Wecker, of Paris; Helmholtz, of Berlin; William Bowman, George Critchett, R. Liebreich, J. W. Hulke, and Soelberg Wells, of London; Donders and Snellen, of Utrecht, Holland.

"It is hoped that many of them will come to New York in 1876. The committee are making all efforts to secure a large attendance, and one that will leave its mark upon the progress of scientific ophthalmology. The co-operation of the profession of the United States in securing these objects is earnestly desired by the undersigned, the Provisional Committee appointed in London in 1872.

"HENRY D. NOYES, M.D.

"DANIEL B. ST. JOHN ROOSA, M.D."

CORRESPONDENCE.

COOL BATHING IN THE TREATMENT OF INFLAMMATORY BOWEL - AFFECTIONS DURING THE SUMMER.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At our meeting in Louisville I promised to give you an account of my treatment, by cold bathing, of children in the febrile forms of diarrhoea during our summer seasons.

It is only barely necessary to call attention to the difference between cholera infantum and the exhaustive form of infantile diarrhoea comprehended under the common name of "summer complaint."

In the first we have those profuse discharges of serous matter from stomach and bowels bringing on a collapse as rapidly and fatally as a true Asiatic cholera; but the latter is slower in its progress, and always connected with fever due to a congestive and an inflammatory process in the intestinal canal, and is very properly designated entero-colitis. This is the affection commonly seen, while the former is comparatively rare.

We know very well that in many of the ordinary affections (summer complaints) the correction of the secretions of the bowels and a change of location to the pure fresh air of the country will bring about a rapid restoration; but among the poorer classes, and with others often, the change is not practicable; then, too, by reason of the tentative measures for their relief ap-

plied by parents and neighbors, many simple cases go on rapidly to a dangerous stage of the inflammatory process before the doctor is called in. We are summoned, in short, very often, to see a child with a hot skin (temperature $102\frac{1}{2}^{\circ}$ – 105°), rapid pulse (130–150) and breathing (30–40), with frequent purging of semi-fluid, greenish, watery, fecal and half-digested matters; the mouth and tongue are dry, the thirst is intense, but the water given to appease it is quickly thrown off, the eyes are staring, pupils contracted, insomnia, rolling the head and uttering distressing cries, due to the headache from hyperæmia of cerebral vessels and the unappeased thirst.

I proceed at once to give the little sufferer a bath in hydrant-water, which with us, in summer, is about 75° .

I have found it necessary to superintend this for the first time myself, as there is great reluctance, if not decided opposition, on the part of many mothers to its use, because the child always screams lustily as soon as it begins to touch the water. I usually direct the feet and legs to be gradually immersed, at the same time pouring water from the hand over the chest and abdomen, until the whole body is under water. Then the head is held in the left hand, while colder water (cistern temperature— 65°) is poured in a continuous stream over the upper part of the head. This is kept up for ten to fifteen minutes. In the mean while the little patient ceases to cry and struggle, and is evidently greatly comforted, more especially if you give it freely of cool water to drink, the greedy swallowing of which shows how much of its distress is due to thirst.

After the bath the child should be wrapped, unwiped, in a thin woollen shawl, and laid upon its bed with a slight additional covering, and it generally falls at once asleep. The skin is cool, the pulse has lost frequency, fulness, and force; the breathing is slower, while the temperature in the axilla has fallen below the natural standard. The reduction may seem at first too great, but reaction soon begins, and a healthy warmth and perspiration are established. The whole scene, in fact, has so changed that you will have no difficulty thenceforth in getting a bath given three or four times a day, if the alarming train of symptoms make show of revival; and they will revive to such an extent as to require exhibitions of the bath from time to time for two or three days perhaps; for the diseased state of the mucous membrane within has not been as suddenly relieved as the abnormal heat of the body.

In the mean time, internal treatment should be vigorously if not heroically practised. Quinine and whisky, beef-tea, milk- and lime-water, are to be freely employed until the fierce symptoms cease to show themselves. One grain of quinine and half to a teaspoonful of whisky every three hours for a child eight to sixteen months look rather formidable, but they will be borne admirably. As the febrile state becomes subdued, bismuth and pepsin should be given every three hours to restrain the diarrhœa and to assist the digestion, so greatly at fault, owing to the blow which the mucous membrane has suffered.

From my experience I am persuaded that under this plan of treatment nearly every case of enterocolitis may be saved.

For cholera infantum, if seen early, give a hypodermic injection of morphia of suitable dose, to be followed up with small doses of calomel and camphor in sugar of milk, until biliary dejections are seen.

Respectfully,

C. G. COMEGYS.

ATLANTIC CITY, June 29, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The present heated term brings with it so surely its annual slaughter of the innocent children confined to close, unwholesome courts and alleys in Philadelphia, that a further notice of our pre-eminent means of rescue for infants of the poor, the Children's Sea-Shore House at Atlantic City, may prove timely and useful. Your own editorial endorsement of the hospital has already set forth its prominent objects (which may also be found in the advertising columns), and I shall, therefore, restrict myself to narrating very briefly the history of one of my young patients, which illustrates the *practical working* of this noble charity.

Ida G., a little girl of German descent, about three and a half years old, has been for some time running down in health, as a consequence of the irritation and discharge from scrofulous abscesses near the knee-joint, and on the 15th of the current month showed very clearly by her sleeplessness, loss of appetite, emaciation, pallor, and tendency to diarrhœa, that a few weeks more of confinement to the hot, foul atmosphere of a large city would probably terminate her frail life. Sea air was advised, and the advice mournfully rejected by her parents on account of their poverty; but at this juncture two charitable ladies, being informed of the circumstances, contributed the small sum required, comprising in all four dollars for two weeks' board, and three dollars fare for the child's mother going and returning twice (generously reduced one-half by the Camden and Atlantic Railroad Company), so that on the 19th inst. Ida was left under the kind and judicious care of Dr. William H. Bennett, at Atlantic City.

Ten days afterwards, on visiting the Sea-Shore House for the purpose, I found it difficult to recognize my poor, pale, fretful little patient in the bright-eyed, rosy, round-faced child, rocking herself in her chair, and singing as cheerfully as if she had never known the poisonous influences of a "man-made town." The change was marvellous; and, to an individual who has not repeatedly tested the life-renewing efficacy, in suitable cases, of iodine, bromine, etc., in ocean water, air, and sunshine, seems almost incredible; but it is one which can, and I hope will, be witnessed by scores of my professional brethren who may try the delightful experiment of sending little sufferers like Ida to this real *Succor of the Innocents* on the shore at Atlantic City.

Very respectfully yours,

JOSEPH G. RICHARDSON.

FORT LEAVENWORTH, KANSAS, April 2, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Please find appended the diagram of an apparatus which I have used successfully in treatment of wound of the tendo Achillis. It consists of a slipper to the bottom of which a plate of iron, extending three or four inches beyond the heel, is riveted. The extremity of this is connected with a broad band passing around the limb below the knee, as represented in the figure. This controls, in some measure at least, the contracting of the gastrocnemius, and I consider it fulfils the indication for treatment of this lesion better than any method heretofore described.

Very respectfully yours,

T. E. WILSON,

Assistant-Surgeon U.S.A.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 22, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

(Continued from page 654.)

Aneurism of abdominal aorta.

DR. JAMES GRAHAM presented the specimen, and furnished the following history:

"H. S., æt. 26 years, married, was a strong, well-made man, a stoker at the gas-works, whom, some four years ago, I attended for chancre and bubo. Since then he married, and has had three children, all of whom suffered from syphilis.

"On the 8th of this month he consulted me in relation to a pain shooting around from the lumbar region to the groin, on the right side, with which he had been troubled for upwards of a month; it was irregularly intermittent, sharp, shooting in character, severe enough to prevent him from working, yet he had not applied for any medical treatment. Six weeks before he had returned from a trip to Antwerp, having worked his passage over as a sailor, and back as a stoker.

"As he lived in a malarious section of the city, I put him on quinine, and ordered him to report at my office in a few days; but on the following day I was called in great haste, and found him pale, remarkably cool and clammy over the entire body, with feeble pulse and violent pain in the præcordial region (severer, he said, than anything he had ever suffered in his life before), shooting to the left shoulder and down to the elbow; also great burning in his stomach. It had come on suddenly while at stool, at nine o'clock in the morning. Stimulants were given freely, heat and mustard-poultices applied externally, and the pillows removed from under his head. He rallied a little, and was more comfortable up to six o'clock in the evening, when the pain again increased in violence; he had to be supported in the

semi-erect posture, and he continued in great agony until his death, at three o'clock the next morning.

"*Post-mortem examination*, fifty-eight hours after death. Rigor mortis well marked. In the thorax nothing abnormal was found, but on opening the abdomen an immense clot of blood was discovered, hiding all the viscera, and reaching from the diaphragm into the pelvis. All the organs were normal, except some enlargement of the kidneys. The cause of the hemorrhage was found to be a ruptured aneurism, the size of an orange, connected with the front part of the abdominal aorta, just above the origin of the celiac axis: it was injured in exposing it, so that the size of the rent could not be determined. The great omentum was distended with blood, and hung down like a bag in front of the intestines. It was uninjured, and we concluded that after the blood had broken into and filled the cavity of the great omentum, it had flowed through the foramen of Winslow into the general peritoneal cavity so slowly as to prolong life for a number of hours."

Dr. JOHN GUITÉRAS asked whether there was caries of the vertebrae, because the pains described generally occur when there is caries. He was reminded of a case where the pains were so severe that preparations were made for section of the anterior crural nerve, when a pulsating tumor in the back was discovered to be the cause of what was thought to be simply a neuralgic affection. The autopsy revealed a large aneurism, with extensive disease of the vertebrae.

Dr. GRAHAM replied that there was no caries.

Cancer of the liver.

Dr. O. H. ALLIS presented the specimen, and read the following report from Dr. MIXSELL, of Easton, Pennsylvania:

"P. R., aged 50, hotel-keeper, sedentary habits. I was called to see him January, 1875. He had then been sick one month. The pulse was found normal, tongue clean, and bowels regular; urine markedly albuminous. There was œdema of the extremities, with serous accumulation in the serous sacs, three pints of turbid serum being drawn from the abdominal cavity. Death occurred in April, possibly from starvation.

"*Autopsy*.—The liver was enormously enlarged; the heart, lungs, and stomach were displaced, and the peritoneal cavity filled with pus and serum.

Fracture of the skull.

Dr. W. S. FORBES presented the specimen, and furnished the following history:

"James McG., aged 22 years, was admitted to the surgical ward of the Episcopal Hospital on the 16th of April. He walked to the hospital from his home, several squares distant. He had been in the dispensary of the hospital three days before, and stated that in a fight he had received a blow on the side of his head with a stick. He was advised to come into the house at once, but he declined doing so.

"When he entered on the evening of the 16th, he was found to have a compound fracture, with slight depression, at the anterior inferior angle of the left parietal bone. During the evening he was dull and stupid, but could be aroused when urged; and, while he could not pronounce his name, he could write it on a slate, and answer intelligently in monosyllables. He was given a purge, and a pledget of lint placed over his wound, with directions to be kept quiet in bed.

"When I saw him, for the first time, on the morning of the 17th, four days after the accident had taken place and some fourteen hours after he had entered the house, there were no symptoms of depression, and he was perfectly rational.

"He was ordered one-fourth of a grain of calomel every four hours, counter-irritation to the nape of his

neck, dry cold to the top of his head, and the wound to be dressed with wet lint covered with oiled silk, and low diet to be given. Under this treatment he continued to remain very well.

"On the morning of the 23d there was a very slight expression of facial paralysis on the left lower side of the jaw and corner of the mouth. One-fourth of a grain of opium was added to the calomel.

"On the morning of the 25th his condition was all that could be desired under the circumstances. Normal pus came from the wound, moderate in quantity; he had no pain, his skin and pulse in good condition. Early on the morning of the 26th there was a sudden change for the worse. The respiration became stertorous, the pulse rapidly rose to 154, and intermittent in a marked degree, a red, frothy matter flowed freely from the right nostril, coma set in, he became cyanosed, and died on the morning of the 26th, about ten o'clock, thirteen days after his accident.

"An examination was made twenty-six hours after death. The membranes of the brain were somewhat congested; there was a depressed, stellated fracture beneath the external wound; the external table of the bone was found extensively fractured, and more depressed than the external lobe, but there was no unusual expression of inflammatory action in the neighborhood of the fracture.

"The left ventricle was filled with serum and some pus. There was a large abscess in the posterior part of the right cerebral hemisphere."

Compound fracture of skull, multiple fractures of vertebrae and ribs, laceration of spinal cord.

Dr. JOHN ASHHURST, JR., reported this case, from notes furnished by Dr. J. C. MERRILL. The patient, a man 22 years of age, was brought to the Episcopal Hospital on the morning of May 3, 1875. About one hour before he had jumped from a train of cars while in motion, striking the parapet of a bridge, and thence falling head-foremost to the ground below. On admission, a small contused wound was found in the scalp, and the latter was separated from the skull over a considerable distance, but no fracture could be detected by the finger. There were slight symptoms of cerebral concussion. Between the scapulae there was a very severe contusion, with extensive ecchymosis, and a general rounded projection of the spines of the upper dorsal vertebrae. There was complete paraplegia, the loss of sensibility reaching to an inch below the nipple on either side. The temperature of the paralyzed parts seemed abnormally high to the hand, but was not tested with the thermometer. There was retention, with partial suppression of urine, but no priapism.

The patient survived about twenty-six hours, having become comatose a short time before death.

An autopsy, which was unavoidably hurried, was made thirty hours after death, and revealed an extensive stellate fracture of the left parietal bone, with slight depression of the outer and greater depression of the inner table. The meninges were congested, but not lacerated, and the brain was normal. There were comminuted and partially impacted fractures of the bodies of the fourth, fifth, sixth, seventh, and eighth dorsal vertebrae, with fractures of the heads of the corresponding ribs on either side. The fourth dorsal vertebra was displaced towards the right, and at a point corresponding to the junction of the third and fourth vertebrae the spinal cord was almost completely severed, its continuity being maintained by means of a mere shred on the right side. The spinal meninges were much congested, and a spicula of bone was found in the substance of the cord. The vertebral canal contained a large quantity of fluid blood. The other organs of the body were not examined.

Cystic mammary tumor.

Dr. ASHHURST also exhibited a large mammary tumor removed a few hours before from an unmarried woman, aged 51. The tumor had originated two years ago, beginning as a small, hard nodule. Very little pain had attended the growth of the mass, which was chiefly annoying from its size and weight. Some portions appeared to be of almost cartilaginous hardness, while in other parts large cysts had been developed, and one of these had ulcerated, discharging a large quantity of sero-sanguineous fluid, and then healing. The tumor was not adherent, and though at the operation it was found to extend around the edge of and to send a prolongation beneath the pectoral muscle, it did not at all infiltrate the adjoining tissues. The tumor appeared to be entirely surrounded with a distinct capsule, the solid portions being of firm, fibrous consistence, and the cyst containing a thin serous fluid together with a considerable quantity of a brownish, honey-like substance.

The specimen was referred to the Committee on Morbid Growths, which reported, May 27, 1875, as follows:

"The Committee on Morbid Growths have examined the large mammary cystic tumor presented by Dr. Ashhurst, and find that certain portions of the cyst-wall presented small secondary cystic formations, which were of an irregular roundish shape. These cavities are lined with a cylindrical epithelium, but, instead of being perfectly smooth, have numerous in-growing papillary projections, giving to the transverse sections a peculiar racemose appearance.

"These cysts have originated from dilatation of the lacteal glands and ducts. They are surrounded by an eminently sarcomatous tissue, presenting in alternating preponderance rounding and fusiform cells. The active proliferation of this sarcomatous tissue has caused it to invade the lumen of the lacteal tubes at points completely occluding them, and thus leading to their cystic distention.

"The growth, therefore, may be pronounced a *cystic sarcoma*, comparatively rare in this site of the body, yet warranting a much more favorable prognosis than can be made in the carcinomatous varieties."

Excision of the knee-joint.

Dr. ASHHURST also exhibited the portions of bone removed in a case of excision of the knee-joint, performed for gelatinous arthritis of one year's duration, in a boy six years old.

REVIEWS AND BOOK NOTICES.

A MANUAL OF DIET IN HEALTH AND DISEASE. By THOMAS KING CHAMBERS. H. C. Lea, Philadelphia, 1875.

This is certainly a most excellent book; avoiding much useless lumber that is common to works of its class, and containing a great deal of valuable information, imparted in a very lively and interesting manner. It is divided into three parts, General Dietetics, Special Dietetics of Health, and Dietetics in Sickness. As we read that part of the first section which treats of the choice and preparation of food, our heart, or rather stomach, longed to dine with Dr. Chambers; but no!—just as we have often found that those who write most strongly against the prevention of conception have the smallest families (probably by a special dispensation of Providence), it may be that our friend's book is better than his dinners. Still, we would like an opportunity of testing the matter.

The second part discusses the proper feeding for

various stations and occupations of life, training, effects of climate, starvation, poverty, etc., and is really very entertaining. The hints to travellers are most timely and practical. Dr. Chambers must have well used his vacations. The chapter on alcohol, whilst we are inclined to commend its defence of the moderate use of the "poison," is the weakest thing in the book; indeed, in its science it is as weak as a homœopathic dilution, and betrays a singular ignorance or an equally singular ignoring of the work of every one besides that of Dr. Chambers.

The section on the dietetics of disease is good, and contains a number of recipes which render it of great value. So far as concerns the work of the publisher, the volume stands on the well-known level of Mr. Lea's books.

SELECTIONS.

PAGET ON GOUT IN SOME OF ITS SURGICAL RELATIONS.—In a course of four clinical lectures published (in abstract) in the *British Medical Journal* for May 15, 22, 29, and June 5, Sir James Paget, after observing that gout is rather found in its typical forms in private than consulting practice, stated that in the latter it has been more carefully studied. There is a large number of comparatively trivial diseases which belong to the gouty constitution, and which commonly pass under the name of incomplete, anomalous, or suppressed gout. Also gout affects the consequences of injuries and diseases other than itself. It is very rare for the offspring of well-marked gouty parentage to pass the middle or elder periods of life without manifesting some degree of the gouty constitution. Gout, too, is greatly modified when it is mingled with other constitutions,—with the scrofulous, the tuberculous, the cancerous, or any other. One of the commonest methods of developing manifestations of the presence of gouty tendencies is an injury. A person with a gouty constitution has a fall or other injury, and in a few days there comes a fit of gout. In such cases there has been a condition so justly balanced that so long as the right nutrition of the several textures is not interfered with they hold their usual course, but that when anything occurs to interrupt the process of nutrition, which makes the various textures feeble, or which tends to bring out any degeneracy, then comes out the special form of disease; for what happens with the gouty occurs also with most other constitutional conditions. As a blow on the breast elicits cancer, so an injury of any kind may bring out gout. If a person with gout about him strike his foot, the gout will appear there; if he wrench his wrist, the attack will come in his wrist. Still more is this likely to occur in rheumatic gout than pure gout. Blows to the hip-joint in such persons are very liable to produce gouty arthritis of that joint. Arnica used externally is apt to produce an erysipelatous condition of the skin in the gouty. Gout, too, modifies many common inflammatory processes; as, for instance, gouty bronchitis, gouty periostitis; and it is of importance to be able to recognize the gouty characteristics in such inflammations. Such gouty tendencies have a tendency to paroxysmal manifestations. The remote consequences of gout after injuries deserve to be carefully noticed. Such persons as are gouty recover more slowly and less perfectly from injuries than others; and in cases where injured parts remain painful, or there is abiding stiffness, gout should be suspected, especially in persons of advanced life.

Gout is sometimes mingled with scrofula. Such is the case in children one of whose parents was markedly gouty, the other markedly scrofulous; and in such pa-

tients inflammation which commences as gout may drift into true scrofulous inflammation. Such cases are very important, and the altering features of the case should be carefully noted and the treatment modified accordingly. Instead of passive movement and shampooing, splints and rest become indicated. Even older persons than children may present such changes. A case occurred lately, in which a person who had long been gouty, and whose tissues were degenerate, was at length attacked with scrofula, which he had escaped in early life. Blended gout and scrofula form a very bad inheritance. Gout, too, exercises an influence upon gonorrhœa and the progress of syphilis. Gouty persons with gonorrhœa are liable to attacks of inflammation in the joints or the sclerotic. Gout mingles, too, with syphilis, especially in its secondary and tertiary manifestations.

Syphilis in a person with blended scrofula and gout will produce a very different series of events from those which the same poison will produce in a perfectly healthy person. Such modifications have been too little studied in connection with syphilis. It might, for instance, be doubted whether syphilis ever produced destructive ulceration of the nose, except in those who were either tuberculous or scrofulous. Again, that form of chronic synovitis that was associated with tertiary syphilis was generally seen only in the gouty. Mercury must be cautiously administered in cases of mixed syphilis and scrofula. For syphilis mixed with gout, iodide of potassium with alkaline waters forms the best line of treatment. Cancer in the gouty is unusually painful, and potash often relieves the pain very effectually.

The minor signs of gout in the hands and feet were next considered. It will not do to build a diagnosis of gout upon any one of these minor ailments alone; the diagnosis must rest upon a number of the smaller features of the case carefully collected and fitted together. If many be found together, or in quick sequence, the diagnosis is almost as certain as if well-marked gouty inflammation of the great toe were found. A very large proportion of the first attacks of complete gout occur in the toe or foot. Less complete forms are common, as darting pains in the toes or knuckles after errors in diet. Still more suggestive is it if the pains be in the heel or tendo Achillis. In the examination of elderly persons, it is quite as necessary to examine their knuckles as their tongue. Gouty hands often look as if they were shortened, especially in the fingers. There are the true globular, rounded, and hot, gouty joints, and also the flattened form of more chronic changes. The palmar fascia is very apt to become affected. A number of old people are seen with their fingers drawn down to the palm, and especially their little finger. If they live long enough, all the fingers may become so affected, the index-finger being least so. Any man who is in the habit of grasping tools tightly is liable to such change in the palmar fascia. Men engaged in lock- and key-making, wire-drawing, etc., are very subject to this condition. Gardeners, and persons who use walking-sticks much, and more so if the sticks be badly shaped, are similarly affected. Such thickenings must not be confounded with the scars of old abscesses or injuries. In gouty cases, the integuments adhere firmly to the palmar fascia. Similar affections may occur in the foot, and often are very troublesome, requiring the boots to be frequently changed.

For the treatment of affections of the fingers and toes, gentle compression, aided by wet linen and oiled silk, is good, and may be continued for the relief of the resultant thickening in the form of a firm bandage. In contraction of the palmar fascia, stretching the hand out on the table several times a day is good.

When the fingers are drawn down, little can be done,

and section of the tendons, if giving temporary relief, is apt to produce greater contraction ere long. Operative treatment will generally lead to a worse state of things than existed ere it was resorted to.

Gout is very liable to affect the nervous system, the sensory rather than the motor nerves, however. It produces intense pain oftener than cramp. This is shown in the intense painfulness of an ordinary gouty attack, a painfulness out of all proportion to the other phenomena of the inflammatory attack, and especially disproportionate to the structural changes in the part attacked. Neuralgiæ, as sciatica and brachial neuralgia, are very common in gouty persons. Various shifting neuralgia in a person of or over middle age should always excite a suspicion of gout. Gouty neuralgiæ are more fitful, more quickly and readily affected by indigestion, errors of diet, and other similar influences, than other neuralgiæ. Then there are some morbid sensations of the skin, even more suggestive of gout. Such are (1) burnings in portions of the skin—hot, burning patches in the thighs, or other parts, as the palms or soles; these sensations, however, are not limited to any particular localities of the skin. The affected portions of skin look healthy, or only slightly flushed; and though the patient complains much of the pain, as burning or scalding, no organic changes appear to ensue. (2) Numbness or tingling of a limb, or of any portion of one—the feeling as if the part was asleep—are also gouty indications, and they may exist for months or years. Such feelings cause great distress in nervous persons, who are afraid that they foretell paralysis or other serious trouble. Paralysis, of course, may be so preceded; the fears in the majority of cases, however, are groundless. Gout should be carefully looked for if these sensations be of long duration in persons whose nutrition is good, and if there be no change of temperature or wasting.

In the hypochondriacal and the hysterical, gout may supply morbid sensations, to which the mental state is only too ready to give color and intensity. The pain itself is real, but those patients aggravate it by errors both of observation and judgment: of observation, because they study it with a morbidly close attention; of judgment, because they assign wrong causes for its presence. Probably there is no special connection betwixt gout and hypochondriasis, but they mutually aggravate each other, and cause much misery which it is often difficult to cure, or, indeed, even to relieve.

Cramps and sudden "catches" in over-action are also found in connection with gout; and in some persons they are, at certain times, almost sure to follow any sustained or awkward movement.

The relations of gout to the urinary organs may be traced in its relations to the lithic acid diathesis. Among elderly persons, a large proportion of cases of lithic acid calculi, and lithic acid gravel, are in those who bear marks of gout; a fact which justifies the assumption that gouty attacks are intimately connected with, if not possibly due to, an imperfect elimination of lithic acid by the kidneys. The appearance of lithic acid or of lithates in the urine is suggestive of gout. Acute inflammation of the mucous membrane of the bladder, with pain and distress, chiefly before micturition, extending to the perineum, rectum, and suprapubic region, and with burning sensations in the urethra, is associated with gout. With these general signs there are more special ones, as the nocturnal occurrence, or dyspepsia, the suddenness of the attack, its sudden subsidence, its relapse, or its metastatic character. Gouty orchitis is not uncommon, and is frequently followed by the presence of fluid in the cavity of the tunica vaginalis. It is prone to relapse; it passes from one testis to the other, and also comes on suddenly. Gout affects the course of urethritis; and in gleet in the

gouty, relapses are apt to follow errors in diet or in drinking. The gouty urethritis is found where there has been no infection, and is itself free from infectiousness. Prostatic disease or enlargement is very frequent in the gouty; so, also, are alterations in the penis. There are fibrous thickening and hardening of the corpus cavernosum, and the changes are similar to those of the palmar fascia described above. The affection is chronic, but harmless. Painful and persistent erections at night are also found most commonly in the gouty, especially in the incomplete forms and with excess of lithates. Bromide of potassium or ammonium is here very useful.

Gout, too, affects the skin, in the form of psoriasis, eczema, urticaria, prurigo, pruritus, etc. The relation is not to be found in any anatomical features, or in any peculiarity of appearance. In such cases the patient's constitution is more important than the anatomical characters of the local disease. For example, if eczema be found in a patient who has had regular gout, there must be a strong suspicion that the eruption depends upon gout, and the case must be treated in this view. Such treatment is as much called for here as in the case of inflammation of a joint in one known to be gouty. The sudden appearance, especially at night, the connection with indigestion or unusual diet, point to the origin. The old rule that such patients should have nothing salt, strong, sweet, or sour, is a good one. The classification of skin-diseases, grown so minute of late, founded mainly on an anatomical basis, leaves out too much the constitutional conditions with which the disease is associated, which is of paramount importance. Ulcers, too, are common in the gouty, especially the eczematous ulcer about the ankle. This is an eczema of which some portion is the seat of thin, shallow ulceration. There is much severe pain, especially on lying down and in bed. In the warmth and quietude of bed the pain becomes agonizing. Such ulcers are commonly associated with varicose veins; not the large tortuous veins, but small clusters of veins, often of bright hue, collected round the ankle or some portion of the leg. Some think the varicose veins the cause of the ulcer, but this view is a fallacy. Incomplete gout is the cause, and the presence of varicose veins is only a coincidence.

Gouty affections of the digestive organs were next referred to. Many persons can foretell the oncome of gout by the appearance of their tongue. Psoriasis of the tongue is also a gouty affection. It is difficult to distinguish this affection from syphilitic psoriasis, and the diagnosis rests on the general environment. There is thin, opaque, white covering over the mucous membrane, like the layer of mucus left by the snail when tracking its way over wood. Diseases of the palate and pharynx are also among the list of gouty affections; and elongated uvula in elderly persons is very suggestive. The gouty dyspeptic is troubled with acidity and flatulence, is easily disturbed by errors of diet, and has "bilious" headache. Often the dyspepsia so induced is accompanied by burning in the knuckles, or in the palms and soles, or by some neuralgia in the scalp. The ready disturbance caused by certain articles of diet in those persons forms a capital diagnostic indication. Gout affects the circulation, and surgically is most seen in gouty phlebitis. It is, perhaps, one of the most frequent of the forms of irregular gout.

Gout, indeed, Sir James Paget remarked, mixes itself with whatever malady is present in the patient. Of course the treatment of a gouty man is different according as it is blended with scrofula or syphilis or occurs in the nervous or the healthy. Colchicum often is useful. There are three things that have to be considered for all gouty persons. First, they should drink an extra quantity of water, especially in the early

morning, before any food is taken. Secondly, those who have lithic acid or lithates in excess should take alkaline instead of pure water. Many waters, as Carlsbad and Vichy, are very useful; and those that are purgative as well as alkaline may be employed when the bowels are confined. Often the skin needs good washings with soap, and thorough rubbing as well as mere warm baths. It is a good plan to adopt the German practice of going to bed for a while after the bath. If English baths were worked with the same care in this respect as is the case abroad, more good would result from them.

In conclusion, he said that what was in his mind was chiefly this: first, the broad general rule that disease is not to be studied as if it could be learned by morbid anatomy alone; and next, that amidst the forms of constitution to be studied in surgery, the gout is an important one, and that it has not only complete and typical forms, but also minor characters, which, if occurring in any number in the same person, or in different members of the same family, might be as sure evidence of gout as the most typical inflammation of hand or toe, and that the gouty element is important in the matter of treatment.—*J. Milner Fothergill, M.D., in The London Medical Record.*

GALLOPING MALIGNANT SYPHILIS.—The presence of two patients in the wards of St. Louis Hospital was the occasion of a clinical lecture on the above malady by Dr. E. Guibout, a full report of which is contained in *L'Union Médicale* of May 25 and 27, 1875.

In contrast with the usual history of syphilis, the secondary and tertiary lesions slowly developing themselves, the two patients under consideration, only six weeks after the appearance of the chancre, were terribly disfigured, and rendered hideous and repulsive, by the enormous black and sanious crusts which covered the greater part of the scalp, face, trunk, and limbs. There were very numerous and very large ulcerations, and from beneath and across the crusts which covered them there flowed incessantly a disgusting mixture of pus and blood. The countenances were pale and thin, eyes lack-lustre, the lips dry, and there was the profound and indefinable expression characteristic of the disease. There was also intense fever, prostration, diminution of vital forces, loss of appetite and of sleep; in short, a general and very severe disturbance of all the physiological functions. In consideration of the phenomena presented by these cases, so different from those usually shown in syphilis, the titles *malignant* and *galloping* have been applied: *malignant* because of the gravity of the cutaneous lesions and of the general condition of the patient; *galloping*, because of the rapidity of the invasion, development, and progress of the local and general lesions.

The form of syphilis under discussion may present itself at two different epochs. It is sometimes *precocious* (*précoce*) or *primitive*, sometimes *tardy* or *consecutive*. The precocious or primitive form occurs when it is the first of the general lesions of syphilis, when it succeeds, with scarcely any delay, the infecting chancre. Such was the form as it appeared in the two cases forming the subject for the lecture. Coming on only six weeks after the infecting chancre, and without the appearance of any other lesion of the skin, there were developed on the head, trunk, and limbs the ulcerations and the crusts of rupia of the gravest form, accompanied with excessive disturbance of the health.

At other times the form is tardy or consecutive. Suddenly, and with alarming characteristics, it supervenes at a late stage of the syphilitic career, after the ordinary constitutional phenomena. There comes over the patient at the same time a change so rapid, profound, and marked that it is impossible not to see something serious is in store.

When we come to consider the cause of the invasion of malignant syphilis, it is found that the late form, that is, that which accompanies the ordinary early cutaneous lesions, or is consecutive to them, is due to the want of proper treatment, to bad hygiene, or to a deterioration of the general health of the patient in consequence of fatigue or of various excesses. The same causes hold good for the precocious, galloping, malignant syphilis. The primary manifestations of syphilis may be malignant if the patient's constitution is poor and his surroundings unfavorable to a healthy hygienic condition.

If the prognosis of syphilis in its most common and benign form is always unfavorable, much more so will it be in the malignant variety.

Its treatment presents great difficulties, and requires all that medical skill and clinical science can command. One needs to consider not only the disease, but even more, perhaps, the patient. Great caution is necessary about prescribing the specifics,—mercury and iodide of potassium. Doubtless these remedies are indicated by the disease, but they are contra-indicated by the state of the patient. In an intensely febrile state, with gastro-intestinal troubles, they would not be tolerated; they would only aggravate the accidents. Above all, the patient must be placed in the best hygienic conditions possible. He should have as much sunlight and out-of-door life as he can endure and the temperature will admit of, together with tonics, opiates, and a generous diet. Later, for the ulcerations and tertiary lesions, the specifics in small doses may be employed.—*Boston Medical and Surgical Journal.*

GLEANINGS FROM OUR EXCHANGES.

ATRESIA UTERI (*Transactions of Ninth Annual Meeting of the Medical Association of the State of Missouri*).

—Dr. Todd reported the case of a young married lady 20 years of age, who had been troubled with dysmenorrhœa ever since reaching the age of puberty, and had never been pregnant. For relief of stricture of the cervical canal, and possibly of antelexion, she had twice, during the last two years, been subjected to operations in one of our Eastern cities. At the first operation the intra-vaginal cervix had been bisected, and the cervical canal incised. For some reason a second incision of the cervix was performed six months after the first operation. After the second operation she menstruated once, without pain and freely; then a second period passed, painful with scanty secretion, and at the next two succeeding menstrual periods there was no effort at menstruation whatever.

At this period in the history of the case Dr. Todd saw the patient. Three attempts were made, with the aid of a strong light, the womb being dragged down almost to the vulva, without discovering any remaining trace of the cervical canal, except the slight indentation where the os externum should have been. The womb was again dragged down forcibly, restoring any possible deflexion of the axis and enabling the operator the better to guide the bistoury in the axial line of the organ. Partly with a narrow-bladed bistoury, and partly with a strong steel probe, an opening was made into the uterine cavity, which was afterwards widened with the hysterotome. A probe was passed to the fundus, showing a depth of one and a half inches, and indicating a small uterus. Tents of soft linen smeared with glycerin were passed daily for a week, after which one of Chambers's uterine stems was passed, and was still being worn. Two menstrual periods had since elapsed, attended with abundant

and painless flow. The stem will be worn until there is no further tendency to contract.

DIVISION OF THE TENDO ACHILLIS IN CERTAIN INJURIES ABOUT THE ANKLE (*Boston Medical and Surgical Journal*, May 27, 1875).—Dr. S. Say reports the case of a laborer, æt. 45, who fell from a step two or three feet high, striking on the pavement on the left side. He was found to have fracture of the left fibula, an inch and a half from the lower extremity. The symptoms were crepitus, increased mobility, and local tenderness. The foot was dislocated on the tibia backwards and outwards, as was indicated by the undue prominence of the heel behind, of the lower end of the tibia in front, and by the inability to flex the foot to a right angle. The internal lateral ligament was partially ruptured, giving a deformity not unlike that seen in equino-valgus. The leg was placed in a fracture-box, but all efforts to remove either the lateral or antero-posterior deformity were unsuccessful. On the fifth day the patient was etherized, and renewed but unsuccessful efforts were made to remove the deformity. The tendo Achillis was divided, and the foot restored to its natural position. The leg was replaced in the fracture-box, the foot kept at a right angle to the leg by a foot-piece, and the lateral deformity removed by side-pads. The subsequent treatment gave very little trouble. The straps and pads required adjusting only once in two or three days, instead of two or three times a day, as before the tenotomy. The patient suffered no pain whatever after the operation. He was discharged five weeks after the injury, when he could walk with a cane, and had only a slight limp. Four months after the injury he reported himself quite well. There is no reason to fear a non-union of the divided tendon, for an ununited tendo Achillis is almost an unheard-of event.

RESIN OF ALOES (*Edinburgh Medical Journal*, June, 1875).—Dr. William Craig has found, by a series of experiments upon man and the lower animals, that the following conclusions are fairly deducible:

1. That aloes may, by exposure to the air, undergo considerable chemical change without losing its physiological action as an active aperient.
2. That the resin of aloes, when thoroughly exhausted of aloin, possesses no purgative properties, and therefore cannot be the active principle of aloes.
3. That the resin of aloes is not the cause of the griping which sometimes follows the administration of the drug.
4. That aloin is an active aperient, and is, in all likelihood, the active principle of aloes; and is sufficient to account for all the purgative properties of that medicine.

Aloin possesses several advantages over the crude drug. Being uniform in strength, its dose can be more accurately determined; its dose being half a grain to one grain, it can easily be introduced into tonic pills without making such pills too large. By using it we get rid of all impurities which are so apt to cause griping.

The following is an excellent pill for the constipation so common to females of a sedentary habit:

R Aloin, gr. ss;
Ferri sulph. exsic., gr. iss;
Ext. nucis vom., gr. ss;
Ext. belladonnæ, gr. ss.

Ft. pil. One or two pills daily.

SUCCESSFUL CASE OF TRANSFUSION (*The Lancet*, June 19, 1875).—A lady, æt. 40, after having had several miscarriages, sailed from New York for France, at a time when she was far gone in pregnancy. She was confined on board the vessel, had considerable hemorrhage, but nursed her child, and succeeded in reaching Paris. There she had severe loss of blood, and was

conveyed to the Maison Municipale de Santé, where the hemorrhagic attacks became more frequent, and she became fearfully anæmic in spite of ergot, brandy, and bark. At last she was so reduced, and the loss of blood so frequent, that plugging, compression of the aorta, and binding up of the limbs were practised; but all to no purpose. Finally transfusion was performed, the blood being obtained from a young ward attendant, in good health, who kindly volunteered his services. About six ounces were thrown into the patient's median cephalic, with a little loss, by means of Matthieu's apparatus. For about thirteen days the greatest care was taken of the patient, and the pulse, temperature, and the proportion of globules were carefully noted. She gradually recovered, and left the hospital six weeks after admission, and thirty-six days after the transfusion, which had been effected with *undefibrinated* blood.

TREATMENT OF OZÆNA (*The Lancet*, June 19, 1875).—In the second number of the new Paris bi-monthly periodical devoted to diseases of the ear and larynx, M. Tillot discusses the subject of chronic rhinitis and its treatment. He justly says that in this respect therapeutics has not kept up with improved means of diagnosis of the condition of the whole nasal tract by means of specula and the laryngoscopic mirror. The method, however, which he pursues, and with a considerable degree of success, is simply as follows: 1, medication directed against the diathetic state of the patient; 2, free cleansing of the mucous membrane from all crusts of inspissated secretion; and 3, direct applications to the membrane. The third object is obtained by means of slightly astringent powders or by the administration of these substances suspended in water and used in the spray-producer. M. Tillot has used for that purpose the mineral water of St. Christian (Basses-Pyrénées), which is a nearly cold, odorless, tasteless water, containing iron and copper, with some traces of iodine and arsenic. He appends several cases both of simple chronic rhinitis and of ozæna, in which the adoption of this plan has led to considerable relief, and often cure. The hint of employing the "spray-producer" is one worth bearing in mind.

OPIUM OR SALICIN IN DIARRHŒA (*Detroit Review of Medicine and Pharmacy*, July, 1875).—Dr. J. C. Bishop, after discussing the physiological action of opium and salicin, and giving a number of cases occurring in his own practice, comes to the following conclusions:

- 1st. Salicin is perfectly harmless, even when administered to very young children; opium is not so.
- 2d. Salicin increases the appetite and promotes digestion; opium destroys the former and retards the latter.
- 3d. Salicin may be administered to the most delicate stomach without any ill sequences, while opium is absolutely contra-indicated in many persons, who possess a peculiar susceptibility to its action.
- 4th. Salicin has no appreciable effect upon the brain, while opium induces a hyperæmia of that organ.
- 5th. Salicin possesses valuable antiseptic properties, while opium, if it possesses any, does so in a very feeble degree.
- 6th. Salicin is an antiperiodic, while opium has no notable effects in that direction.
- 7th. Salicin prevents the putrefactive changes in the contents of the bowel; opium does not.

CROUP AND DIPHTHERIA (*The Lancet*, June 19, 1875).—Dr. Wm. Carr calls attention to the following case as aiding in establishing the proof that a primary fibrinous croup may exist which has nothing in common with diphtheria as an infectious disease, and which not uncommonly follows and is the sequence of a catarrh of the larynx.

A boy, suffering from measles, was admitted into the Charité, with laryngeal catarrh strongly developed, and

yet there was nothing to be seen in the throat beyond simple angina. The hoarseness, however, continued for some days, even after the diminution of fever. After four days' duration the temperature rose, and in a few hours croup was developed, for which tracheotomy was performed. From the aperture in the trachea a long plastic tube of membrane was drawn out. The canula was retained for ten days, and the child recovered. Such cases prove that true croup may be developed from a catarrh; but it must be confessed that at the present time cases of true croup compared with those of infectious diphtheria are of rare occurrence.

PATHOGNOMONIC SIGN OF LUXATION OF THE HUMERUS.—Professor Dugas, some years ago, described in the American Medical Association a new method of diagnosis in luxation of the shoulder-joint. The subject has been recently revived in the *Nashville Medical Journal*, which gives the following description: "If the fingers of the injured limb can be placed by the patient or by the surgeon upon the sound shoulder while the elbow touches the thorax, *there can be no dislocation*; and if this cannot be done, there *must* be a dislocation. In other words, it is *physically impossible* to bring the elbow in contact with the sternum or front of the thorax if there be a dislocation; and the inability to do this is *proof positive* of the existence of dislocation, inasmuch as no other injury of the shoulder-joint can induce this inability."

MISCELLANY.

PHOSPHORUS-POISONING.—Some interesting experiments have recently been made by MM. Thiernesse and Casse on the value of injections of oxygen into the veins as an antidote to phosphorus-poisoning, and they found that its power of neutralizing the toxic effect was very great, the symptoms of poisoning soon ceasing. The poison was in some cases injected into the veins, dissolved in oil, in others administered by the mouth. The oxygen was at first injected dissolved in defibrinated blood, but it was found that the quantity of oxygen that could be introduced in that way was insufficient to counteract the poison. The injection into the veins of pure oxygen, however, was perfectly successful. The experimenters found it necessary that the gas should be pure, free from all admixture with air, and that it was requisite to introduce it slowly into the circulating current. The quantity necessarily was large, several hundred cubic centimetres being required for an animal weighing twenty pounds. The precise apparatus employed is not described.—*London Lancet*.

LOW TEMPERATURE FROM EXCESSIVE DRINK.—Dr. Shattuck (*Boston Medical Journal*) reports the case of a man who at one time drank *three champagne bottles full of brandy*; how much more is not known. Twenty-four hours after this spree he was found comatose in a freight-car. The temperature, taken in axilla and rectum, by at least two thermometers, was 76° Fahrenheit. Twelve hours afterwards it had come up to 91° Fahrenheit. He entirely recovered.—*Detroit Review of Medicine*.

A CHARITABLE WISH.—Dr. Grabham, in a lately published pamphlet on the "Origin, Varieties, and Terminations of Idiocy," relates that one of his lady

correspondents, the mother of a patient, writes to him that "her late husband used to say that there was no such place as hell, but she hopes now he has found out his mistake."

It is stated that nearly all the men selected for the British Arctic Expedition are of a fair complexion. Scoresby's test was an ingenious and probably a good one. Each candidate was obliged to stand with his bare feet upon a cube of ice, and those who endured longest were chosen.

WARTS.—Dr. Guttceit recommends rubbing warts night and morning with a moistened piece of muriate of ammonia. They soften and dwindle away, leaving no such white mark as follows their dispersion with lunar caustic.—*Eclectic Medical Journal*.

By a vote of 138 to 27, the English House of Commons recently granted two thousand pounds sterling for medical researches. When will our Congress grant the first cent?

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 6, 1875, TO JULY 12, 1875, INCLUSIVE.

HEAD, J. F., SURGEON AND MEDICAL DIRECTOR.—Leave of absence extended twenty-five days. S. O. 21, Military Division of the South, July 8, 1875.

COOPER, GEO. E., SURGEON.—Granted leave of absence for one month and fifteen days, with permission to go beyond the limits of the Division. S. O. 79, Military Division of the Pacific, June 25, 1875.

STORROW, S. A., ASSISTANT-SURGEON.—Assigned to duty at Benicia Barracks, California. S. O. 63, Department of California, June 23, 1875.

MATTHEWS, W., ASSISTANT-SURGEON.—Assigned to duty at Alcatraz Island, California. S. O. 63, c. s., Department of California.

HALL, J. D., ASSISTANT-SURGEON.—Relieved from duty in the Department of Dakota, to report to the President of the Army Medical Board, New York City, for examination for promotion, and, at its conclusion, by letter to the Surgeon-General. S. O. 135, A. G. O., July 8, 1875.

The following promotions and appointments in the Army of the U. S., made by the President, are announced.

APPOINTMENTS—MEDICAL DEPARTMENT.

To be Assistant-Surgeon, with the rank of First Lieutenant, to date from June 26, 1875.

BLAIR DABNEY TAYLOR, of New York.

CURTIS ETHELBERG PRICE, of California.

JAMES CHESTON WORTHINGTON, of Maryland.

HENRY STUART TURRILL, of New Mexico.

EDWARD TIFFIN COMEGYS, of Ohio.

WALTER REED, of Virginia.

HENRY SAYLES KILBOURNE, of Indian Territory.

JAMES CUSHING MERRILL, of Massachusetts.

WILLIAM RICHARDSON HALL, of Missouri.

RICHARDS BARNETT, of Mississippi.

GEORGE HENRY TORNEY, of Maryland.

LOUIS WILLIAM CRAMPTON, of Pennsylvania.

JOSEPH YATES PORTER, of Florida.

MARSHALL WILLIAM WOOD, of Illinois.

MARCUS ELVIN TAYLOR, of New York.

WILLIAM LANDS NEWLANDS, of California.

JOHN DE BARTH WALBACH GARDINER, of Maryland.

ROBERT E. SMITH, of Missouri.

WILLIAM CUMMINGS SHANNON, of New Hampshire.

GEORGE EDWIN LORD, of Maine.

LOUIS S. TESSON, of Missouri.

WILLIAM GARDINER SPENCER, of New York.

ROLAND LEE ROSSON, of Virginia.

G. O. 69, A. G. O., July 2, 1875.

SATURDAY, JULY 24, 1875.

ORIGINAL COMMUNICATIONS.

CHLORAL.

BY W. B. ATKINSON, M.D.

THOUGH discovered by Liebig as early as 1832, chloral was not brought into use as a remedial agent until Liebreich introduced it early in 1869. Since that time it has rapidly grown in favor, and at one time appeared in danger of assuming the position of a panacea.

Dr. Squibb says, "It supplies another forcible illustration of the baneful effects of speculation and inflation, and of the dangers which must always attend popularity; and particularly the popularity of potent medical agents. It seems hard to teach the public that nothing can be potent only for good. That to be potent for good involves, in the very nature of all things, an equal potency for harm. Hence the danger of advertising any medical substances which have any potency for popular use, . . . for the chances are always greatly in favor of the substance doing more harm than good, until a panic and prejudice are produced against it, when it may be unjustly condemned and lost."

These remarks of Dr. Squibb forcibly remind us of the fact that when in California, in 1871, we found chloral in almost universal use: persons with no pretence to any medical knowledge were constantly employing it in large doses for the relief of the neuralgic pains to which a large majority of those dwelling on the Pacific coast are subject.

This article derives its name from the first syllables of the two bodies from which it is made,—chlorine and alcohol.

It is prepared by passing for several days *dry* chlorine gas through *absolute* or very strong alcohol, until hydrochloric acid ceases to be produced. On cooling the liquid, a partial solidification takes place, due to the almost unavoidable hydration of the chloral. The mass is now treated with strong sulphuric acid, the oily liquid which separates is distilled over a little lime, and the distillate is combined with the requisite quantity of water, and then allowed to congeal, or else crystallized by fusion and slow refrigeration, or from one of its solvents.

At present, the hydrate of chloral, commonly known as chloral, with the exception of the croton chloral hydrate, which has only very recently been discovered, also by Liebreich, is the only form used: the alcoholate and all other forms having virtually disappeared.

Much of the difference of results obtained by the early uses of this agent we feel confident arose from the vast difference in the purity of the article. Indeed, so great was the diversity of opinion, that one might have concluded with good reason that an entirely different article had been under observation. At present, pharmacists agree that the surest method to procure a pure form is to have it recrystallized.

In this form it is found in distinct, colorless, transparent crystals, dissolving readily in water, producing a clear solution, and is much less liable to cause that irritating effect so often noticed by those who employ it.

Prof. Jos. P. Remington, to whom we are indebted for valuable suggestions, proposes that this form only should be prescribed, under the name "chloral (recrystallized)."

The limits of an essay like the present forbid the entering more into detail upon the chemistry of chloral; but we shall prepare a bibliography which will prove of service to those who desire to investigate these points more fully. Among the best articles that have appeared is one by Prof. E. R. Squibb, published in the "Transactions of the Amer. Pharm. Assoc." for 1871.

This gentleman, in a private letter, says,—

"Although its popular use has diminished very much, I judge by my own experience that its professional use is still steadily increasing, and its sphere of utility is gradually enlarging. I supply it to about five of the largest insane hospitals in the United States, and have done so for many years, and find the quantity used steadily but slowly increases, whilst its value and utility seem best established where it is most used, because where most used it is best understood. I believe that those who are most timid in regard to it are mistakenly so, and are those who use it least. And those are most timid in regard to it who most frequently misapply it. I think that as a simple, safe, and valuable hypnotic it has a sound, well-deserved, permanent reputation, and fills a place in the *Materia Medica* which was before vacant."

He also says, "In a case of obstinate vigilance, the result of excessive brain-work, in which I am now advising and watching its use in a prominent man, it is doing most admirable service, having broken the habit of inability to sleep. And now, in smaller and smaller doses, it is re-establishing the normal habit of sleep, which is quite as necessary as food is to brain-work."

Because of the fact that chloral is decomposed by the action upon it of alkalis, liberating chloroform, it has been supposed that a similar action takes place in the system, and that its medicinal effects are due to this supposed presence of chloroform in the circulation. Recently, however, this has been denied: and several experimenters have been unable to detect chloroform in the blood of animals or human beings while under the influence of chloral.

As a sleep-producer we have found it invaluable, inducing a most refreshing slumber, from which the patient may readily be aroused, and into which he relapses as though he had not been disturbed. We have, after the experience of its use in a large number of cases, not once observed any unpleasant results; never headache, occasionally a slight nausea, due, we were led to believe, to the impurity of the drug. We have yet to see a case where its use was interdicted by any idiosyncrasy. Of course, our remarks are intended to apply only to its use in proper medicinal doses, as it has never been our

ill fortune to see an instance where it has been administered in excessive or poisonous doses.

The cases reported from time to time, where it has been taken in extreme doses, show that it produces first a deep sleep, gradually followed by coma and death. What would prove, however, a poisonous dose to some seems to have acted medicinally in others, as cases are on record where enormous quantities have been swallowed in a very short time and apparently without any untoward results. When under its full effect, the whole muscular system is relaxed, a result which has been found of great value in many instances. For this reason it has been proposed as a substitute for chloroform, ether, and the other anæsthetics. Upon this point we shall speak subsequently.

In the latter part of 1871 we first employed this agent in a case of acute mania from the use of alcohol. We exhibited it in full doses, say twenty grains, repeated every hour until sleep was procured. Having a careful and reliable nurse, we left the patient after administering the first dose, and on returning, after an interval of a few hours, we found our patient sleeping quietly. He had been suffering at short intervals, prior to the use of the chloral, with terrific convulsions. All trace of these had disappeared. He had taken, we believe, four doses: eighty grains. The change was so marked, and his sleep so profound, that his wife expressed a fear lest he should never awake. Having reassured her, we left, to return next day. In this interval, the nurse was under instructions to repeat the dose if the patient should wake and show signs of a convulsive tendency or of mania. He slept most profoundly all night, anxiously watched by his wife and the nurse. In the morning, as the wife again expressed her fears, we roused him, and had some nourishment administered. He awoke readily, replied clearly to all our questions, and again sank into sleep without a renewal of the dose, and slept in the same way until late in the day. From this time he rapidly recovered.

Our experience in this case emboldened us to its further use. We felt assured that it was *the* remedy for convulsions, and determined to employ it should it be our misfortune to encounter any cases of puerperal eclampsia. Having made this suggestion to a number of our friends soon after, Dr. Wm. F. Patterson called us to see a case where the convulsions had set in soon after delivery, and in which he had already been employing the remedy. Examination of the medicine convinced us that the chloral was of an inferior quality; we immediately administered a double dose, and ordered a new supply from an undoubted source. Our next meeting showed a good result. The convulsions had ceased, and the patient was enjoying a pleasant, refreshing sleep. Convalescence was rapid.

Since then several similar cases have occurred to us, and in every instance has this remedy demonstrated its power for good.

Among those who allude to its value in these cases are Schroeder and Leishman, both of whom speak highly of it.

Mazona regards it as a preventive of eclampsia,

and says it procures a repose strongly favoring the cure of this form of convulsion. He remarks, "Puerperal convulsions, of whatever nature, are calmed by chloral; it never aggravates the paroxysms, but the patients are always found better after its administration. In eclampsia it is necessary to keep the patient under its influence sufficiently long. It should be repeated on the slightest sign of a return of the paroxysms."

Although a few writers have failed to obtain good results, yet, as each is limited in his experience to a single case, we cannot allow this to weigh against the host of instances reported where it has proved its value and saved the life of the patient.

Obtain a pure article, administer it in full and frequently-repeated doses until the convulsive tendency is subdued; then act according to circumstances.

In some cases we have procured a cessation of the convulsion by the anæsthetic effects of ether or chloroform, and immediately administered a full dose of chloral. When it is found impossible to cause the patient to swallow, the remedy may be administered by the rectum, in the form of an enema. Of course, the dose should be increased, say forty to sixty grains at first, the effect carefully watched, and the enema repeated, or the remedy given by the mouth, if this becomes practicable, as may be demanded by the exigencies of the case.

In these and similar cases it has been used in the form of a subcutaneous injection, or of an intravenous injection, as proposed by Prof. Ore.

In this connection we might allude to the report of this gentleman to the Academy of Sciences of Paris, of several cases in which he has succeeded in producing anæsthesia by this plan. In one diseased bone was removed from the tibia, and in the other ovariectomy was performed. He adds a few drops of a solution of carbonate of sodium to a mixture of one part chloral and four parts pure water. Dr. Lande followed this plan with a fatal result.

As it can best be administered in solution, it becomes important to disguise its burning, acrid taste. We have invariably ordered the syrup of orange-peel for this purpose, and believe this, when rather concentrated, will prove the most effectual means of covering the taste.

Capsules have been proposed, but these would positively be objectionable, by liberating at their point of solution the agent in a concentrated form, which would be sure to give rise to extremely unpleasant if not dangerous results.

The range of diseases for which this remedy might be employed with advantage would naturally suggest itself after the above description of its properties.

Especially in parturition has it proved of immense value. In our "Hints in the Obstetric Procedure," we have already assigned to it its proper position. In lingering labor, we have been greatly pleased with its action. All who have employed it agree in saying that its effects are most happy. Perhaps we cannot do better than quote from Prof. Carl Schroeder. He says, "Chloral appears to act in a manner similar to opium. Gerson da Cunha

has given it in tardy and exhausting labors; after a few hours' sleep, on awakening, the labor was very rapidly terminated by powerful pains. We have also observed that by the use of chloral in cases where the uterine action was very painful without being effective, the labor assumed an instantaneously rapid course, although the intervals between the pains had considerably increased in duration."

Further, he says, alluding to its anæsthetic properties, "It appears that chloral has until now been used only in a limited number of normal labors. Lambert recommends it strongly, but he prefers it in small doses of fifteen grains every quarter of an hour to a larger dose given at once. It by no means interferes with the contractions of the uterus, but rather favors them."

Schroeder says, "We can bear testimony to this from our own experience. For even if by its use the interval between the pains becomes somewhat lengthened, the pains themselves increase in efficiency."

In these views of Schroeder and others we fully concur, having constantly had recourse to it, both in our own practice and in consultation. In every instance have we had reason to be satisfied with its results. The detail of one case will serve as a type of all.

Mrs. G., in labor with her twelfth child, was found in much anxiety, because of the fact that all her labors had been tedious, painful, and exhausting. The os was rigid, the pains powerful, and everything betokened a tedious time. We gave her a dose of fifteen grains, to be repeated hourly, if the pains remained the same. She took two doses, had a refreshing sleep of three or four hours, was aroused by full labor-pains, speedily terminated by a natural delivery. She remarked that she had never experienced so easy a labor. All who have employed it at our suggestion bear the same testimony as to the results obtained. In this connection, we find the views of Mazona so fully expressive of these effects that we must be excused a quotation. He says, "With females in labor, chloral brings first calm, then sleep. It considerably diminishes the pains. The uterine contractions continue during the chloral sleep. They are shorter, less frequent, but more powerful. In general the length of the labor is shortened by the chloral. It places the patient in a semi-conscious condition; yet it may be so complete that she may be entirely unconscious, even at the moment of delivery. This anæsthesia is prolonged after the delivery, for a time. Given in small doses, it produces agitation, which ceases when the full dose has been administered. It may be administered at any time during labor."

We have frequently had occasion to observe its value in cases where, near the close of pregnancy, the patient would be attacked with pains simulating those of labor. A vaginal examination would reveal an undilated os, and an entire absence of the accompaniments of real labor. Here the exhibition of one or two full doses of chloral will send the patient into a profound, refreshing slumber, from which she awakes with renewed life, and may often

continue comfortably in the performance of her usual household duties for several days. We have invariably observed that when our patient fell into labor after such treatment, her progress to delivery was rapid and pleasant.

As might have been anticipated, this remedy has been largely used in puerperal mania, and with the most excellent effects. Combined with the bromides, it speedily controls the acute symptoms, and in the few cases which we have encountered recovery was rapid and permanent. Prof. Fordyce Barker has found it of immense value. He says, "It apparently does not interfere in the slightest degree with any of the organic functions; it is not followed by any unpleasant secondary effects, as opium often, and bromide of potassium sometimes is; and in mania I have never yet seen it fail to induce sleep."

Prof. Barker thus compares it with chloroform: "Whatever chemists may tell us, I am certain that the effects of chloroform and chloral-hydrate differ in many essential particulars. Chloroform induces a very profound sleep, but this is of short duration. If the patient be awakened, she does not fall asleep again without a renewal of its administration. The sleep from chloral-hydrate is prolonged often for hours, and if awakened while under its influence, the patient at once falls asleep again. After the sleep of chloroform there is frequently cerebral disturbance for a few moments after waking, as there is also just before the subject comes under its influence. The sleep from chloral is neither preceded nor followed by symptoms of cerebral excitement. Chloroform is of immense value in preventing and controlling convulsions, but is of no service in producing sleep and allaying excitement in the maniacal. The chloral has very little, if any, influence in preventing or controlling convulsions (which we deny, gentlemen, from our own experience), but is by far the best agent known for inducing sleep in puerperal mania. I usually prescribe it in fifteen- or twenty-grain doses, well diluted, to be repeated every two hours until the effect is produced. I have given it in thirty- or forty-grain doses, but I have now settled on the smaller quantity, as being safer and just as efficacious, if repeated until the desired influence is obtained."

Leishman observes, "Chloral is another remedy which has of late, to some extent, superseded opium in the treatment of insanity, as in many other diseases; and experience seems to show that in this drug we have a most important addition to the materia medica of the class of diseases in question."

In other forms of mania, especially in delirium tremens, has it proved potency for good. The case alluded to in the opening of this paper is a fair type of the results to be expected from its employment. In full doses, at short intervals, until sleep is procured, it is vastly preferable to opium or any of its preparations.

For the morbid vigilance of mania, we believe all alienists agree as to its value.

In general practice, we find it extolled in bronchial affections, for allaying cough and procuring rest for

the diseased organs; in a number of such cases our own experience has been very happy. Watson regards it as often preferable to opium, which sometimes acts in a dangerous manner. In asthma, it relieves the spasmodic trouble, though we have not observed that it gave any immunity to a fresh attack. In pertussis, in quite small but frequently-repeated doses, it generally shortens the attack, and anyhow makes the disease less exhausting to the little sufferer.

Weidman, of Jena, reports a case of chorea completely and readily cured by this agent alone.

In epilepsy, its administration has acted to relieve the force of an attack, but does not seem to prevent a return. As yet, however, the number of cases reported are so few that we are unable to deduce any positive inference on this point.

In tetanus, Verneuil, Dufour, Denton, and others have successfully administered chloral, and we find fresh cases are constantly reported where it has acted favorably. Anstie says of it in spinal irritation, "in moderate doses it is probably the best and safest remedy, and with care not to give too much, we may go on using the same dose without increase for a good many times."

Nor are we restricted to its use internally, for we find it to possess valuable properties as an external application. Combined with an equal part of camphor, by prolonged trituration it forms a thick oily fluid, to which six or eight parts of glycerin or simple ointment may be added. This makes an excellent application for the relief of pain, irritation, and itching; particularly is it useful in cutaneous troubles.

Dr. L. D. Bulkley recommends this application very highly in the "Transac. Amer. Med. Assoc. for 1874," under the name of "A New Antipruritic Remedy."

Of course it is necessary to see that the skin is not broken, else this application will produce, as in our own experience, the most intense burning pain, which may result in a high form of inflammation.

As an external wash, Martineau suggests a solution of one part to a hundred of water for bed-sores. He bathes the part, and covers it with lint saturated in the solution. He says, "Its action is remarkable. The sore which was indolent takes on a new appearance, healthy points appear, it suppurates less and heals rapidly." He treats suppurating cysts with injections of chloral water, and when the pus is fetid, he adds the eucalyptus. Dujardin-Beaumetz also announces good results from this same mode of application.

From this view we might anticipate its use as an antiseptic, and we find several writers proposing this. Perhaps the best paper on this application of chloral is that by Dr. W. W. Keen, in the *Medical Times*, March 21, 1874.

For the purposes of dissection he found that its cost would preclude its general use; but it is preferable for delicate dissections, as it preserves the color and the natural consistence better than other articles; enables subsequent injections into the arteries to be made with better effect, and does not prove so destructive to instruments.

For pathological purposes it is cheaper, and at the same time renders the preparations more accessible, than when preserved in alcohol.

In surgery, he found it a most thorough deodorant, and a stimulant of indolent ulcers into healthy granulating sores. If too strong, it becomes a powerful irritant; the best proportion is two to ten grains to the ounce. The odor, if found objectionable, may perhaps be entirely overcome by the addition of an essential oil.

When applied to the mouth or nostrils, as in ozæna, the solution must be very weak. The best plan is to commence with a small quantity, say one-quarter of a grain to the ounce, and increase as may be found necessary. In no case should it be repeated when its use is followed by great irritation.

In our clinics at the Howard Hospital, we have used it in a large number of cases of leucorrhœa, etc., and in nearly every instance with great benefit. Several writers report cases of gonorrhœa rapidly cured by injections of such a solution, increased in strength until it produced slight smarting.

Time will not permit our dwelling at more length upon the uses of this agent, but enough has been given to show the range of symptoms it is best able to combat.

We desire, in conclusion, to refer to some of its contra-indications, and to the effects produced by a too long continuance in its use. This is always to be deprecated. In one instance, to relieve intense hyperæsthesia, where every other remedy had failed, it was ordered, and, in desperation, the lady repeated the dose at extremely short intervals, occasionally increasing the quantity. While it effectually allayed the extreme sensitiveness, it produced a species of mania, lasting for about twenty-four hours, and she still complains that it has affected her memory. In this case, we did not observe the rubeolous eruption said to be caused by its long use or in poisonous doses.

Manning has seen it to cause a hyperæmia of the skin, and an erythema over the face and chest, which Brown-Séquard attributes to a temporary paralysis of the vaso-motors of the head and neck. If continued, it will extend to a paralysis of the extremities. He relates two cases of mania with very intractable insomnia, in which he gave five grains twice a day to one, and double that to the other, followed by thirty to forty grains at night. After seven or eight weeks of this treatment, the patients had become so feeble as to be unable to walk, or to put one foot before the other. This rapidly disappeared when the chloral was discontinued.

Gubler speaks of its effects as chloralism, which he divides into acute and chronic. The slight form of the acute is characterized by vomiting, vertigo, hebetude, loss of force, and various eruptions. The grave form is followed by pallor, troubled vision, cold sweats, feeble pulse, stupor, coma, tetanic convulsions, and death. Chronic chloralism exhibits symptoms similar to ergotism, as hyperæsthesia, general uneasiness, epidermic desquamation of the fingers, superficial ulcerations around the nails, anasarca, albuminuria, feebleness of the heart, embarrassed circulation. These often terminate in death.

From the experience thus far obtained, it would appear that in certain individuals this remedy is contra-indicated by the existence of an idiosyncrasy in certain cases, and by general feebleness of constitution. Its use has been frequently objected to in cases of great irritability of the stomach. In our own experience we have never regarded this. In a case of intussusception, the physician had failed to give relief by any of the remedies employed. In consultation, we suggested chloral in free solution, repeated at short intervals. Our next meeting found the vomiting entirely checked, the pain relieved; in short, the patient rapidly convalesced from that hour.

As an antidote to the poisonous effects of this remedy, strychnia has been proposed. M. Ore has experimented upon these remedies, and arrives at the conclusion that this view is erroneous. On the contrary, Dr. L. Turnbull, who has experimented also, recommends, in cases of impending death from this agent, the system should be supported by heat, food, and artificial respiration, with stimulation and small doses of strychnia.

In this connection we cannot refrain from giving his conclusions, as drawn from experiment and observation. There are three degrees of the operation of chloral: first, feebly soporific, with slightly nervous sedative action; second, deeply soporific, with diminution of sensibility; third, complete anæsthesia, loss of general sensibility and muscular power,—catalepsy. Death takes place last at the heart, which remains in action long after the death of the other organs. The heat is reduced one or two degrees when under its influence. In affections of the eye, it is apt to cause swelling, redness, excessive lachrymal flow.

This lowering of the temperature has caused several writers to suggest its employment in the pyrexias, as variola, scarlatina, etc., where the temperature is above the normal rate. Of course, much will depend upon a more careful investigation of this point before a positive decision can be made.

In conclusion, gentlemen, while thanking you for your patient attention to my paper, the limits of which I fear have far exceeded the bounds of propriety, let me say that I shall feel fully repaid for any effort it may have cost me if I can impress upon you the inestimable value of chloral as an aid in the obstetric art.

EXCRETION OF ALCOHOL THROUGH THE RESPIRATORY TRACT (Schmidt: *Centralblatt für Chirurgie*, No. 23, 1875).—Heubach has recently confirmed the previous opinion that in febrile affections none, or but little, of the alcohol which is administered re-appears in the urine, and Schmidt has, in pursuance of similar investigations, sought to find the amount of spirit of wine contained in expired air.

The alcohol was always given four or five hours after the last meal, and during the time of the experiment the nose was closed by means of a clamp.

These experiments were carried out on ten patients, and to each of them at least fifty cubic centimetres were administered; but in no case could evidence be obtained of more than a trace of alcohol in the expired air.

W. A.

TRANSLATIONS.

PERIODIC MELANCHOLIA (Nefstel: *Centralblatt für Chirurgie*, 1875, No. 22).—Dr. Nefstel calls attention to a variety of melancholia which has not as yet been fully described, and which he thinks presents some characteristics the study of which may throw some light both upon the genesis and the treatment of the affection. A banker, aged 48 years, whose mother had melancholia sine delirio, has suffered since 1851 with attacks of melancholia of a periodical character which last from four to eleven months and are followed by periods of two to five months of comparative health. These attacks appear to occur entirely without cause, and are at first made manifest by irritability of temper, etc., which is followed after the lapse of a few days by the development of the most intense and painful depression.

The patient, who is a very intelligent man, complains of loss of energy, apathy, and anxiety, and is incapable of any exertion. These complaints are made, however, only when inquiries are made as to his condition, for if not disturbed his relation with the outer world is entirely passive.

In conjunction with this mental state, the appetite is impaired, constipation is present, there is restlessness during the unrefreshing sleep, and the patient becomes weaker and loses flesh. Finally, the symptoms become almost unbearable; sleep is almost impossible, and the gravest consequences seem imminent, when suddenly the attack passes off, and a state of normal health supervenes, which continues for some months until the next attack of the disorder.

Owing to the number of attacks which came under observation, the following facts relative to them were established:

1. There was always a loss of weight during the attack, which was made up as soon as a return to health took place.
2. Each attack began with a subacute anæmia; the skin and mucous membranes were pale, the pulse small, slow, and contracted, and the veins dilated.
3. There were also present during the attacks many evidences of perverted nutrition,—boils, eruptions and itching of the skin, falling of the hair, etc.
4. At the climax of the attack, all the secretions were markedly diminished, and evidences of derangement of the vaso-motor system were noticed.

From all this the inference seems allowable that there was an anæmic state of the brain, or, perhaps, of only certain parts of it, with which the other symptoms can be brought into accordance.

W. A.

FUNCTION OF THE THALAMI OPTICI (H. Nothnagel: *Centralblatt für Chirurgie*, No. 23, 1875).—After destruction of the thalami optici in rabbits, the animals stray about, still preserving the power of voluntary motion, neither paralysis nor anæsthesia being noticed, there being at most some loss of flesh after the expiration of some weeks. When, however, there was actually a total destruction of these organs, this result was abnormal, since the animal then allowed the fore-legs to remain in anomalous positions when thus placed. When the injury to the brain had been unilateral, this phenomenon was noticed only on the extremity of the opposite side of the body. Destruction of the thalami, as a rule, added nothing to the symptoms observed when some of the adjacent parts had been injured, but in some cases when the injury had been but partial in its character, in addition to a bending of the vertebral column and nystagmus, the head was held towards one side.

From these observations it is fair to conclude that neither the routes via which impulses to voluntary

motion are transmitted, nor those which transmit sensation, pass through the thalami optici. The only positive disturbance which manifests itself after removal of these parts of the brain is a failure, under certain conditions, to retain the extremities in their proper position. Motor phenomena also occur in the thalami, which are excited by peripheral sensory impression.

• Nothnagel then agrees with Maynert in regarding the thalami as the organs by which co-ordinated motions which are reflex in character and follow peripheral impressions are made possible. These in their turn pass from the thalami to the exterior of the front and sides of the cerebrum, become fixed in the ganglion-cells of these parts, are remembered, and serve in their turn as impulses to conscious action. W. A.

INTRACELLULAR DEVELOPMENT OF BLOOD-CORPUSCLES IN MAMMALIA (*Centralblatt für Med. Wissens.*, No. 22; from *Proc. of Royal Soc.*, 1874, E. A. Shaefer).—The subcutaneous connective tissue of the new-born rat consists principally of a hyaline substance which is nearly homogeneous, and in which but few fibres, together with a considerable number of unusually delicate flattened cells, are present. The protoplasm of these last-mentioned bodies contains very numerous small, bright bodies, which probably contain a watery fluid, since they have less refractive power than the hyaline substances.

These frequently conceal the nuclei which are almost always present in the contents of the cell. From these cells the blood-vessels of the tissues and their contents, the red, and probably also white, corpuscles originate. Before the development of these intra-protoplasmic bodies to red blood-corpuscles has been completed, the cells containing them grow in length, and the hæmoglobin finally lies in a cavity. The cell resembles a section of a capillary tube, but with pointed and closed extremities. It has a drawn-out, spindle shape, and consists of a hyaline wall, in which the nucleus is imbedded, and contains blood-corpuscles and a fluid that is blood.

Two or more cells of this kind unite at their ends, and, a communication having been thus established between them, by a similar process a union is formed with capillaries which already exist, and in which the blood is already in circulation. It is worthy of remark that this junction of these spindle-shaped cells is not effected by a direct juxtaposition of their respective extremities, but the end of one overlies that of the other, and then the communication is caused by the absorption of parts of their walls. W. A.

THE USE OF THE LARYNGOSCOPE AMONG CHILDREN (*Centralblatt für Med. Wissens.*, No. 25, 1875; from *Jahrb. f. Kinderk.*, T. viii., Klemm).—The laryngoscope can readily be used in the examination of the throats of children of three or four years of age, and local applications can also be made without disturbing the youthful patients. Among these remedies the use of solutions more dilute than when intended for adults, applied with smaller pencils, is advised in preference to that of powders applied by currents of air. With the exception of croup and diphtheria, diseases of the throat and larynx are of much more rare occurrence among children than among adults, and many affections which are common among them are unknown among the young. Among such may be mentioned chronic catarrh of the pharynx and larynx, and also syphilitic and tuberculous ulcerative processes, as of much less frequent occurrence in extreme youth than in adult life.

Klemm never saw primary laryngeal phthisis in a child, and concludes either that youth is in itself a protection against this affection, or that the exciting causes which play their part among adults are here wanting.

Reliable observations relative to the frequency of paralysis in childhood are wanting, but disturbances of sensation seem to be entirely absent. In the same connection Klemm remarks that he has treated hypertrophied tonsils in children, with good results, by boring into them with crayons of nitrate of silver. W. A.

TWO CASES OF CHOREA WITH FATAL TERMINATION (*Centralblatt für Med. Wissens.*, No. 25, 1875; from *Gaz. des Hôp.*, 1874, De Beauvais).—The two patients were both girls, aged 14 years, but, on account of the pathological conditions found, the second case seems to be more worthy of detailed report. The girl's development had been good, and nothing abnormal about her was noticed, except some twitching of the facial muscles during her second year. The first menstrual epoch passed without any disturbance, but during the second the patient fell into deep sleep, and, after having been awakened, symptoms of chorea of the most marked character came on, which steadily increased in severity until death occurred.

The brain appeared to be increased in volume, its membranes red, and in the great longitudinal fissure they were somewhat thickened and could not be readily separated from the cerebral substance. The convolutions lay close to one another, and were of a rosy color. The gray substance appeared to be reddened, and the vessels of the pia mater and of the white substance were too full of blood, while in the ventricles was found a serous fluid which was mingled with blood. The cerebellum was also hyperæmic, and on its under surface the gray substance was found to be somewhat softened. The membranes of the cord were also found to be very rich in blood, and the substance of the cord very soft and yellowish white in color, and confluent at the level of the upper dorsal vertebra. The lungs, heart, kidneys, liver, spleen, intestines, and stomach were healthy. W. A.

ACTION OF ACONITE ON THE HEART (L. Lewin: *Centralblatt für Med. Wissens.*, No. 25, 1875).—The conclusions reached by this experimenter are as follows:

1. The anomalies in the heart's action which occur in poisoning with aconite do not have their origin in an affection of the medulla oblongata.
2. The observed results, which are apparently contradictory, can be separated into two groups, both of which include a lesion of the nervous centres in the ganglia of the heart, and are distinguished by there being in one class an integrity of the pneumogastric nerves which does not exist in the other.
3. The integrity of paralysis of the vagi depends upon whether its intracardial terminations have been merely irritated for some time or actually paralyzed.
4. This variation is entirely individual in character, and does not depend upon the poison.
5. The rhythm of the pulse which has been frequently observed is to be explained by the unequal and irregular action of the aconite on one or other of the cardiac centres, and this may be due to an unequal distribution of the poison in the blood. W. A.

SALICYLIC ACID IN CATARRH OF THE URINARY ORGANS.—Dr. Paul Fürbringer gives an account, in the *Berliner Klin. Wochens.*, 1875, No. 19, of four cases in which salicylic acid was used internally to combat alkaline fermentation of the urine.

The first case was that of a phthisical and paralyzed young man, whose urine was alkaline, fetid, threw down a voluminous precipitate of triple phosphate, urate of ammonium, and pus-corpuscles, and contained an innumerable number of bacteria. He was ordered fifteen grains of the acid in a mucilaginous potion daily, and after three days the urine showed an acid reaction with much less odor. The use of the acid

for a longer period removed all the sediment, but the death of the patient put an end to the observations. The second and fourth observations were in general much the same; but the third case, that of a man who had suffered for years from chronic cystitis, was treated by local injections or rather by washing out the bladder with a one-fifth per cent. aqueous solution of salicylic acid by means of a double catheter, the internal use of the acid being simultaneously continued. The improvement in all these cases, as indicated in the change from alkaline to acid reaction, in clearing up of the sediment, and in diminution and death of the bacteria previously found in the urine, points to this remedy as efficient in such affections as bring about alkalescence of this fluid. Dr. F.'s conclusions are as follows:

1. Salicylic acid administered internally in relatively small doses prevents alkaline fermentation in the urine.
2. It does not, however, prevent the secretion of pus in the urinary passages. X.

MOVABLE KIDNEY.—Dr. Fourrier communicates to the *Bull. Gén. de Thérap.*, June 15, the notes of six cases of this affection, accompanied by remarks.

The patients were all females, the first three having passed the epoch of the menopause, the last three still menstruating. In each case the right kidney was the one affected. The symptoms in the first series were colic in the region of the kidney,—transient, and occurring at irregular intervals; in two of the cases nephritis, and in all three a tumor painful to pressure, presenting the form of the kidney, and situated or extending into the right iliac fossa.

In the second series of cases the physical signs were similar, and the symptoms very much the same, excepting that the attacks were coincident with the menstrual epoch, the patient being quite free from suffering in the interval, and in one case the trouble disappearing entirely after the cessation of menstruation. In one case a peculiar oily film which covered the urine after standing was noticed.

Dr. F.'s cases were all more or less relieved as to the painful symptoms, by tonic or other treatment. He recommends perfect rest during the menstrual period when this seems to predispose to the attacks, with attention to the digestive functions and the nervous conditions apt to accompany the affection. Finally, a supporting bandage should be used; occasional frictions with iodine may be of use, and care should be taken by the patient to avoid sudden shocks, as in stepping down or jumping. Any anæmia which may be present should also be combated. X.

OPERATIVE PROCEDURES IN RETENTION OF URINE FOLLOWING CONTUSION OF THE PERINEUM.—During a debate on this subject at a recent meeting of the Société de Chirurgie, M. Notta asked if the surgeon, when called to a case of this kind, should make a supra-pubic puncture to evacuate the urine, or should seek to evacuate the bladder by the ordinary route. In three cases coming under his care he had followed the latter method, making an incision into the urethra on the median line of the perineum, and, introducing a fine whalebone bougie into the open ends of the urethra, had used this as a guide to the catheter. The wound in each case cicatrized nicely, and nothing remained but a slight narrowing of the urethra, which it was easy to remedy later. M. Guyon remarked that his custom was to cut directly down upon the urethra without making any previous attempt at catheterization. External urethrotomy in cases of stricture certainly presents difficulties; but in cases like those under discussion, when the urethra preserves the normal direction, it is easy to cut down upon it. M. Le Fort made a distinction between those cases in which effusion of blood alone took place, and those in which extravasation of urine also resulted from tearing of

the urethral walls. In the former variety simple puncture of the bladder was often sufficient, and the urethra subsequently regained its patulous condition.—*Bull. Gén. de Thérap.*, June 15. X.

OXYGEN AS AN ANTIDOTE TO PHOSPHORUS (*Centralblatt für Chirurgie*, No. 23, 1875).—The question arose at a recent sitting of the Académie Royale de Médecine of Brussels, whether or not the antidotal effect of the crude oil of turpentine against phosphorus might not be due to contained oxygen. (It should be said that the rectified oil is valueless.) In order to settle this point, MM. Thiernes and Casse undertook a series of experiments upon dogs who had been poisoned with large doses of phosphorus. Defibrinated and arterial blood was injected, and direct intravenous infusion of oxygen gas was also practised. The former means failed entirely to give relief, and these observers then turned their attention entirely to the trial of oxygen infusions. The operation is not without risk, but, as these cases are desperate, it is justifiable. Injections were made into the external saphena vein by means of an apparatus especially devised for the purpose. The results obtained on the whole were highly satisfactory, and lead to the belief that oxygen is the essential antidotal constituent of the crude oil of terebinthina. X.

CURE OF MALIGNANT PUSTULE BY CARBOLIC ACID.—The various means of treatment which have been used in *pustule maligne* may be divided into two classes: those intended to destroy as promptly as possible the charbon virus at the point where it has been inoculated, and those aimed at the prevention of the general effects of the poison. In order to destroy the virus locally, caustics of every kind have been used; while to fulfil the second indication tonics, stimulants, diaphoretics, and sometimes evacuates have been employed. Dr. Estrader has employed carbolie acid both internally and externally with the greatest success in six cases, which are published in the *Bull. Gén. de Thérap.* for June 15.

TREATMENT OF ALOPECIA BY ELECTRICITY.—Dr. Waldenstrom has attempted to remedy the loss of hair from the scalp by this means. He applied in one case one of the poles to the superior ganglion of the great sympathetic, and the other upon that portion of the scalp from which the hair had fallen. At the end of six weeks the hair was replaced. Another patient treated in the same manner showed a not less favorable result at the end of two months of electrization. In spite of this double success, Dr. W. does not feel authorized to extol the remedy without further trial. He only states his belief that the treatment is a promising one, and hopes it may have a thorough examination. X.

A NEW METHOD OF ADMINISTERING ENEMATA OF CHLORAL.—M. Dujardin-Beaumetz has employed the process suggested by Griffith for administering chloral enemata, with success. A solution containing a drachm of chloral is beaten up with the yolk of an egg, and this is added to a glass of milk to form the enema. This mixture has the advantage of causing no pain, which is not the case when doses of thirty to sixty grains of chloral are administered in the usual enema or suppository.—*Bull. Gén. de Thérap.*, June 15. X.

SOLUBILITY OF SALICYLIC ACID (J. Müller: *Berlin. Klin. Wochens.*, 1875, No. 19).—Salicylic acid is soluble in three hundred parts of water, in four parts of alcohol, in fifty parts of hot oil, and in the same proportion of hot glycerin, without precipitation on cooling. Glycerin aids its solution in water, so that this will take up one part to three hundred, provided the acid is first dissolved in twenty parts of hot glycerin, and this mixed with eighty parts of water.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 24, 1875.

EDITORIAL.

CIRCULAR No. 8.

WE have recently seen it stated that in the Western towns india-rubber pavements are highly esteemed on account of their extensibility,—a mass meeting of the oxen of the place being held every spring, and the pavements drawn out a few yards or rods according as the town has grown less or more. The word “circular” appears to suffer the same violence as the india-rubber pavement. Johnson shakes his huge head at the use of it as a noun, standing out for a “circular letter;” Webster, more in unison with the modern spirit, grants the employment of the single word as an abbreviation of a “circular letter or paper;” but now the power of the United States Government is invoked, and the unfortunate noun, pulled and dragged out of all shape, reluctantly and brokenly encompasses a huge quarto of nearly seven hundred pages. It is marvellous, but we wish the strength of this great republic were bent to some better task than that of spoiling the King’s English.

Circular No. 8 is indeed a lusty volume, full of much sound sense, and evidently born of much labor. Just here, if our readers will pardon us, we would like to ask a question. Why is it that, dubbed *soldier*, the average Anglo-Saxon American willingly bestows upon the government for a mere pittance an amount of intelligent work and sterling integrity which in civil life would bring a rich reward,—ay, and does not even begrudge life itself, —whilst the same Anglo-Saxon, yclept *politician*,

spends his nights and days in endeavoring to discover how much he can get out of the same government with the least possible labor?

To return to Circular No. 8. It is a report upon the hygiene of the U.S. Army; a reply to a general order issued from Washington last year, in which the medical staff of the army was requested to furnish reports upon the special hygiene of the various posts, and the general hygiene of the service,—barracks, hospitals, rations, clothing, personal cleanliness, military punishments, and other matters being pointed out for detailed discussion.

The book opens with a very able introduction of the whole subject by Dr. Billings, in which are said many things, both new and old, of interest to all interested even in civil hygiene; especially is this true of that part of the introduction in which the subject of hospital construction is discussed and the plan of a model military hospital given. We would most highly commend the detailed researches of Assistant-Surgeon Charles Smart upon the constitution of the air in the buildings at Fort Bridger.

Different companies of the same regiment were quartered in buildings closely associated, but very diverse in the quality of their contained air, as was shown by repeated chemical examinations. Composed of as nearly as possible precisely similar men, under the same medical care, eating of the same food, exposed to the same weather, and doing the same work, one company had twice as large a proportion of sick as the other, seemingly entirely because of differences in the ventilation of their quarters.

The main portion of the “circular” is taken up with the reports of the medical officers of the various posts, supplemented by elaborate meteorological tables extending over four years, compiled at Washington, under the superintendence of Dr. Woodward. The information here given is of the most detailed character, and embraces everything affecting the health of the soldier. Of course this is of the utmost value to the military service of the country; but the book is scarcely less valuable to the civil profession.

As the report enters into the consideration of the climatology of the posts, the effects of high elevations upon disease, the endemic diseases and general medical geography of the neighborhoods, and as the posts extend over the whole country, from the extreme southern point of Florida to the ice-bound coasts of Alaska, it is evident that the volume is a grand foundation for a proper study of the medical geography of the United States, and renders it possible to answer at an early day many of the various

questions which grow out of the relations of localities to disease. Especially is this the case because of the unbiassed condition of the observers. The judgment of a physician of Colorado or of Florida, of the proprietor of some Virginia sulphur spring, or of the possessor of a free pass upon the Atlantic City Railroad, bears with it the odor of prospective fees; but the average army-surgeon is a nomad; the whole country is his home, and his bread is like that of the righteous,—sure, though it be not overmuch in quantity.

In conclusion, as a motion to adjourn is always in order, so it seems to us is every opportunity fitting to urge upon Congress to do justice to that staff, which, whether viewed by the fruits of its labor or by the culture of its members, is second to none. The present volume is an eloquent though dumb protest against longer ignoring the claims of our confrères of the army. Is not he who preserves the life of one of our own army of as much value as he who takes the life of an enemy? Rifled cannon are good in their way, but hygiene is no less important. The destroyers and the saviors, let them walk hand in hand.

MEDICAL PRESS AND CIRCULAR.—This highly respectable Irish journal has been frequently accused of being in its general management hostile to the United States; but we have never perceived any evidences of such unfriendliness. It is ridiculous to be over-sensitive to criticism; and undoubtedly the American profession, although open to criticism, can well afford to learn its defects as seen with foreign eyes. Our Irish contemporary now, however, certainly owes to its own dignity as well as to its Irish readers a thorough retraction of the ludicrous lies with which its American correspondent has recently occupied its columns. So far as America is concerned, it makes little difference whether these statements are or are not allowed to stand, since here the journal will only be laughed at; but with regard to Ireland it is different, for there the statements may be believed. The truthfulness of "our American correspondent" is shown in the following extracts:

"Thousands, yes, millions of infants are yearly murdered by criminal abortion by these men. This shows forth most glaringly the shocking and awful depravity of American women, and men too. You are probably already aware that the Americans tolerate only one or two children at most. As soon as a wife discovers she is pregnant, she either goes to the abortionist or sends for him, and without any more ado commits the abortion. Among this large and motley

crowd of 'dark and evil ways' must be classed *most* of the 'female doctors.' These are terrible-looking creatures,—veritable witches, if such beings exist at all on this earth,—and who do a thriving trade in abortion."

We have only one word further to say to these statements; it is simply this: any respectable journal which has inadvertently allowed them to be made in its columns has only one course left consistent with the maintenance of its respectability,—to retract them, and to discharge its correspondent as a man utterly unworthy of confidence.

THE Evansville Academy of Medicine seems desirous of enforcing ethics *vi et armis*. It has passed a by-law that whenever a member's name appears in the daily press in connection with an operation, the member shall publicly deny that the statement was made with his consent; or, in the event of his failure to do this, charges are to be preferred against him by the censors.

LEADING ARTICLES.

HÆMOGLOBIN IN THE URINE WITHOUT ALBUMINURIA—ITS DETECTION BY THE GUAIAECUM TEST.

IT is commonly thought that the presence in the urine of the coloring-matters of the blood is invariably attended by albumen, and such is indeed the case when the hæmoglobin is sufficiently abundant to impart a hue to the urine, or be detected by the more ordinary tests, including the microscope. But in an admirable article on "The Etiology of Bright's Disease and the Pre-albuminuric Stage," by Mr. Fred. A. Mahomed, published in vol. lvii. (1874) of the *Medico-Chirurgical Transactions*, it is shown that hæmoglobin may almost invariably be demonstrated by the guaiacum test in acute Bright's disease before albumen makes its appearance. This condition is accompanied, and apparently caused, by a high degree of tension in the arterial system, as shown by sphygmographic tracings.

Mr. Mahomed's method of procedure is as follows: One end of a small slip of white blotting-paper is dipped into the urine and dried over the flame of a spirit-lamp. By this means the dilute solution of the crystalloid is concentrated by evaporation. Two drops of the tincture of guaiacum are then dropped on the paper, and, after a minute or two allowed for evaporation, a single drop of ozonic ether is let fall in the centre of the guaiacum stain. Some time, perhaps a quarter of an hour, will elapse before the blue becomes visible, especially if the reaction is slight. And when it appears it is not permanent, but will begin to fade in a few hours, and will have disappeared in a day or two.

Care must be taken that the urine is not contaminated with saliva, nasal mucus, or iodine, as is the case when a patient is taking a salt of iodine. The guaiacum and ether must be fresh, and Mr. M. suggests that they and the blotting-paper should be tested to guard against any contamination that might give rise to a fallacious result, this being the case with some blotting-papers. With these precautions observed, however, the test becomes most easy of application, the physician having only to carry a few slips of the clean blotting-paper, one end of which he dips into the urine and dries, while on the other he can record the name of the patient.

The reaction is said to be even more brilliant when the guaiacum is applied directly to the urine in the following manner. A drop or two of urine is placed in a small test-tube, to which is added *one* drop of the tincture of guaiacum and a few drops of ether; the two are agitated, and the ether then allowed to collect at the top, forming an upper layer, into which, if *hæmoglobin is present, the blue color is carried*, leaving the urine colorless below.

The practical application of this test, although limited, is of the greatest importance. The reaction can be obtained only in the earliest stage of acute or chronic Bright's disease, usually before albumen appears or when it is present only in the most minute quantity. It occurs in chronic albuminuria only when blood is present in the urine, and, when this occurs, the guaiacum test gives by far the earliest indication of its presence. The reaction fades when albumen becomes copious, and appears again as it diminishes or after it has disappeared. By watching the urine by this test in a case of scarlatina, an attack of acute Bright's disease may be averted by a prompt action upon the bowels, a wet pack, or a cupping over the kidney, or all combined.

PROFESSOR TRAUBE.

"THE world-renowned Professor Traube, Privy Counsellor, died at Berlin on the 24th ult., in the 57th year of his age, after a brief illness."—*Allg. Wien. Med. Zeit.*, June 8, 1875.

Traube was born in Ratibor, Upper Silesia, in 1818. After graduating at the university of his native town, in 1835, he entered upon the study of medicine, completing his course at the University of Berlin in 1840, having occupied one year less in winning his diploma than the six years which he so earnestly advocated as the shortest allowable period of medical study prior to graduation.

The reception of his degree opened the way to broader studies. During his entire professional career Traube was an enthusiastic student, unflagging in intellectual energy. Medicine was his life, and medical literature has been greatly enriched by his discoveries, by his lucid theories, and especially by his scientific method of study.

He was famous as a Latin scholar, and his extensive library was crowded with Latin medical writers, from

whom, in his lectures, he constantly quoted, in the original, with the utmost fluency.

His experience as a teacher began very early, how early is uncertain, but for more than twenty-five years he was connected with the Charité Hospital of Berlin, as physician, lecturer, and, finally, as University Professor. He became renowned as one of the keenest, coolest, most skilful, most honest clinicians and diagnosticians in Germany, and was called in consultation even to cities far removed from Berlin. He was a clinical lecturer to whom it was a delight to listen; for at his hands a case became fascinating, such were his clearness and thoroughness. He had the faculty of bringing quickly into view the leading symptoms, followed by minute details which only genius could discover, and which would hardly have been missed if his quiet allusion to them had not revealed their value.

His audiences were composed not only of students and young physicians, but also of wise, mature men, who were glad to come and learn of him. He was a favorite teacher not alone because of his great talent, but because he was *honest*. He never misled others to shield himself, as is done by teachers who were his contemporaries. No man is infallible; and if subsequent events revealed to Traube the slightest error in his previous assertions, his students were at once made aware of it, with clear and good reasons for his error. But he rarely erred. His keen diagnostic insight rendered him almost clairvoyant.

The results of his life-work have been given to the world in his famous "*Beiträge*,"—a collection of his medical papers, comprising three volumes, which should be in the hands of every physician. Unfortunately, they have never been translated. Another work, "*Symptoms of the Diseases of the Respiratory and Circulatory Apparatus*," was begun by Traube in 1868. It was to have appeared in five parts, only one of which has been published, a loss which cannot be sufficiently regretted.

For many years one day with Traube was like another. From 7 to 9 A.M. he was in his laboratory; 9 to 12 at the hospital with his classes and patients; 12 to 4 P.M. he devoted to consultation and private practice (his lunch being hastily eaten in his carriage); 4 to 7 were his hours for office-practice, every moment of which was occupied; then came his dinner-hour, after which a brief recreation with his family, and then a plunge into medical studies, which lasted far beyond midnight.

Traube had two moods,—his hospital and his social mood. At the hospital he was intense in his devotion to his cases, becoming so absorbed as to have offended more than one visitor by what seemed a discourteous manner, which was well understood by those who knew him.

In the home he was winning, gentle, cordial, hospitable; silent at times, perhaps, in the weary later years of his life; suffering, too, from the cardiac affection which was the probable cause of his death, but never speaking without the smile which made his face radiant.

It was a pleasure to sit at his table, for the simple, unclouded geniality of Traube, and the charming hospitality of his wife, created an atmosphere which one did not willingly leave.

Those who know him through his books will entertain the deepest respect for Traube's memory; but to those of us who knew him personally, who have been the recipients of his courteous and kindly hospitality, and have felt the charm of all that made him lovable, this is a loss which adds to our affection for him the sad element of sorrow.

H. O.

PHILADELPHIA, July 8, 1875.

CORRESPONDENCE.

NEW YORK, July 9, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At the same time that the autopsy was being made in the case of aortic aneurism at Roosevelt Hospital, of which we gave some account in our last letter, Dr. Robert Weir, one of the attending surgeons, had three operations for ununited fracture in the amphitheatre. Two were of the bones of the forearm, and one of the tibia, and all the fractures had been treated outside the hospital.

The main surgical ward at Roosevelt is quite a model in its way. It is in a one-story pavilion, quite a distance from the rest of the building (though connected with it by a covered passage-way), and is as bright and airy a place as one could wish to see. So perfect is the ventilation that even in winter there is seldom or never any of the characteristic hospital odor, which, until quite recently, was always regarded as inseparable from such institutions.

The following notes, taken on a casual visit to the ward, will show something of the ordinary run of cases and the methods of treatment practised in the service of Dr. Weir.

1. Abscess of groin, in an old man. This was not a venereal bubo, and, as it was not traceable either to psoas or to sacro-iliac disease, it was somewhat difficult to account for its causation. Dr. Weir regarded the case as interesting on account of its rarity. The abscess had been evacuated, and was now being packed with oakum.

2. Fracture of lower extremity of tibia, involving the malleolus. In cases like this, with little tendency to displacement, the solution of silicate of sodium, or liquid glass, makes the best splint. The bandage saturated with it can be accurately applied to the part, and it makes a lighter and less cumbersome dressing than the plaster of Paris. It is also recommended for affections of the joints on this account.

3. Amputation at middle third of fore-arm. The patient had had his hand mangled by the cog-wheels of a planing-machine, and when admitted to the hospital it was simply hanging by a shred. In such cases it is always best to amputate some distance above the seat of injury, on account of the bruising of the mus-

cles (as shown by the ecchymoses on the skin), as well as the splintering of the bone in many instances.

The operation had been the circular one; hemorrhage being controlled by the Esmarch method. It was now the third day afterwards, and an erysipelatous-looking blush was seen extending up to the elbow, and in streaks of redness even some distance above it.

Dr. Weir lays great stress on the proper drainage of the stump in amputations, and thinks one great element of the wonderful success achieved by Mr. Callender, of London, is his method of introducing between the flaps a silver tube, like a catheter. An india-rubber drainage-tube may also be used with equal advantage. The stump in this case is dressed daily with a solution of salicylic acid, and cloths wet with the same are continually kept over it. The man has been suffering from traumatic fever, due either to the shock from the injury or to the amputation; most probably the former. Last night the temperature was $103\frac{1}{2}^{\circ}$, and this morning 101° .

4. Swelled testicle (orchitis and epididymitis). In adults this affection is almost universally due to gonorrhœa, though in children it is not unfrequently met with as a concomitant of gravel or stone in the bladder. In this case, however, it was due to injury; the man having struck his genitals against the back of a chair while engaged in fencing. It has been treated simply with a lead-and-opium lotion.

In the early stages, when there is great pain, nothing is so good as the continuous application of the ice-bag, as first suggested by Dider. The hyperplasia and hardening resulting from the affection may be left entirely to time. It was formerly always the custom to strap with adhesive plaster; but this is now given up to a great extent, on account of its often being extremely painful to the patient, as well as really unnecessary. Prof. Van Buren has used with success the oleate of mercury, externally applied, to hasten absorption.

5. Gummy tumor of the leg. It is two inches in diameter, and situated over the anterior surface of the tibia, in its lower third. It is of a dull-red color, gives a distinct sense of fluctuation, and hypodermic exploration reveals the presence of clear serum in it.

The patient was in the hospital once before for the same; became considerably relieved, and went out. He now also has a gummy elevation on the right clavicle, which is quite painful. There is marked paralysis of the right upper extremity and slight loss of power in the lower extremity of the same side, due, in all probability, either to a syphilitic tumor of the brain, or to an exostosis or node on the cranial tablets pressing upon the cerebral substance. Treatment, large doses of the iodide of potassium.

6. Fracture of the patella. This has been treated by a long padded back-splint; while in front two straps of stout cotton cloth, one of which is securely fastened by a roller to the limb above the knee, and the other below it, are buckled securely together just over the seat of fracture. The fragments can thus be drawn firmly together and kept in apposition; and Dr. Weir does

not regard it as necessary any longer to keep the limb elevated.

Very firm ligamentous union has already been obtained in this case, and, as the patient will soon be discharged, he was warned to be particularly careful in going over uneven ground. Persons who have had one patella fractured are very liable to have the other one broken also under such circumstances, on account of the extraordinary strain upon the sound one.

7. Stenosis of the glottis (syphilitic). Laryngoscopic examination shows this to be due to gummy infiltration and ulceration, and the calibre of the opening is so considerably diminished as to produce very great difficulty of respiration. The man says he was once under treatment for the same at the Liverpool Infirmary. He is taking large doses of the iodide of potassium (twenty grains four times a day), and seems to be improving.

Such cases as this often call for tracheotomy, which fulfils two important indications: 1, it rescues the patient from impending suffocation; and, 2, it gives the larynx complete rest, thus allowing the reparative process to go on undisturbed.

At the last meeting of the Board of Aldermen the ordinance in relation to muzzling, capturing, and killing of dogs during the summer months was called up for consideration, and, after some debate, defeated by a considerable vote. This was probably due to the outside influence brought to bear upon them. In the first place, the indefatigable Mr. Bergh had addressed a letter to the Board, in which he spoke of the extreme rarity of true hydrophobia, of the powerful effect of the imagination when the idea of hydrophobia is prevalent, and of the fact that dogs were really more liable to the disease in winter. Last year in this city, he said, there was substituted a most pernicious moral disease for a rare physical disorder; the effect of which was peculiarly depraving to the rising generation. The law directly encouraged robbery and blackmailing, and the reward given for every dog brought to the pound tempted the boys to collect them from the country and bring them into New York. In conclusion, he alluded to the "good old times" under Mayor Hall, when the health of the city compared favorably with its state at the present time, and recommended a masterly inactivity on the dog question. The Board of Health also passed resolutions to the effect that in their opinion the regulation requiring muzzles to be placed on dogs during certain months of the year, with a view of preventing hydrophobia, is inadequate, and that statistics show that more general provisions are necessary, and such as should be enforced throughout the year. The resolutions also requested that the Board of Aldermen should give to the Board of Health an opportunity to present a report and the requirements of a suitable law upon this subject. In advocating them, Dr. Janeway, the newly-appointed Health Commissioner, remarked that this muzzling of dogs in summer-time is a popular delusion, and that the public mind becomes unnecessarily agitated about hydrophobia by such

action. Medical statistics show, he said, that hydrophobia is exceedingly rare, and that dogs are more susceptible to it in winter than at any other season.

Notwithstanding all the vast amount of talk on the subject, the Harlem Flats nuisance still remains unabated, with the exception of the partial disinfection mentioned in our last. It having been doubted whether the Board of Aldermen really had the power to authorize the Commissioner of Public Works to act in the matter, and, if they had, where the money was to come from to enable him to carry out his plans, the Board of Health, taking advantage of the extraordinary powers granted them in cases of emergency, have ordered that the whole pestilential region be covered with fresh earth to a height not less than two feet above high water, and that the surface be so graded that no water shall stand upon it; and have called upon the Board of Estimate and Apportionment to appropriate the sum of \$60,000 for the expenses of the work. At last, therefore, something seems likely to be done about the matter. It is a disgraceful fact that the Commissioners of Charities and Corrections, notwithstanding all the outcry about it, are even now permitting this same garbage which raised such a stench on the Harlem Flats to be used in filling in the low, marshy ground at the east side of the upper end of Blackwell's Island; on which they propose to erect pavilions for the accommodation of the increasing number of epileptic patients now in hospital. A pleasant prospect, certainly, for the poor epileptics.

That the public baths are appreciated by the poor is pretty well attested by the fact that on one day last month, just after they had been opened for the season, no less than twenty-five thousand persons availed themselves of the use of the only two we have. They must have been terribly overcrowded, and it really seems too bad that New York cannot have a larger number of free baths; for at present but a very small proportion of the population can enjoy the inestimable advantages which such establishments afford. The baths were open 124 days last summer, and there were 749,560 bathers, or an average daily attendance of about 6000, one-quarter of the number being females. No person is admitted to the baths without a ticket, and tickets may be refused for sanitary or police reasons, when deemed necessary.

The number of people who can comfortably bathe at the same time at each of the two baths is about sixty, and the average time allowed to each bather is only ten minutes, though the rules prescribe twenty minutes. In admitting persons to the baths a line is formed, and when a sufficient number to fill the bath have entered, the doors are closed until there is room for new-comers. Before and after working-hours the crowd is said to be enormous, and many have to wait for hours before they can obtain admission. All of which shows how urgent is the demand for increased bathing-accommodations for the people.

Some little time since, an exhibition was given in the City Hall Park of what is known as Galibert's Respiring Apparatus, designed to preserve life amid smoke or foul air of any kind. It consists of a canvas

bag of about the size and shape of a half-barrel, and containing twenty-five gallons of air, which is worn upon the back; being held in position by two straps encircling the arms. Two flexible tubes pass from the bag and terminate in a mouth-piece, and the nose is closed by a clasp, while the eyes are covered with glass protectors. A large pine box having been set up and filled with a dense cloud of smoke, three young men, wearing the apparatus, entered successively, and remained in it fifteen, eighteen, and twenty minutes respectively. They were in excellent condition when they came out, the only change in their appearance being a considerable redness of the face. The air in the bag is said to be sufficient for thirty minutes' respiration, and it is claimed that many lives can be saved by firemen being thus enabled to reach every room of the largest tenement-house (no matter how dense the smoke) and remove the inmates. One of the commissioners and a number of the engineers of the Fire Department were present, and expressed themselves as highly delighted with the success of the experiment.

PERTINAX.

BENICIA BARRACKS, CAL., July 4, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In your issue of June 19, quoting from the *Union Médicale*, you refer to the finding of twelve young sharks in the abdomen of the parent by M. Lesseps, also the confirmatory evidence of Dr. Moinet, of the French navy.

While on duty at Fort Jefferson (Dry Tortugas), Florida, I saw a female shark, fifteen feet long, caught and brought on shore by the men of the command, and on opening her abdomen I found *thirty-one* young sharks, averaging thirteen inches long, as lively as young kittens, and, although entirely sightless, on being put in the wet ditch they swam about for several hours. Their blindness was proven by their striking repeatedly against the scarp and counterscarp wall. Two of them were alive the morning following the capture of the parent.

I cannot agree with Dr. Moinet that boiling was the best way for their destruction. Like Macbeth, being from their "mother's womb untimely ripped" would have made their lifetime very short; far too much so to have left any idea of injury from them in the future. A more merciful course might have been followed.

S. A. STORROW,
Assistant-Surgeon U.S.A.

AMPUTATIONS WITHOUT HEMORRHAGE THROUGH THE USE OF THE ÉCRASEUR.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—As experiences concerning hemorrhage in operations performed by means of the *écraseur* seem to differ so very much, and as, judging from my own clinical observations, these differences find

explanation in the manner of working the apparatus, and in the time given to the manipulation, I will ask the space required for a paragraph to note that, by slow screwing, conjoined with frequent stoppages, I have, within the past few weeks, twice amputated the tongue, and the same number of times the penis, without occasion to use a single ligature; not less than half an hour being consumed in any of the cases, and as much as forty-five minutes in one of the operations on the penis; the ablation in this instance being made close to the body.

Having used the instrument under many conditions where hemorrhage was the trouble to be anticipated, and having enjoyed in its employment a most satisfactory series of results, I am led to entertain a conviction that success with it resides in slowness of motion, conjoined with stoppages of from one to two minutes, frequently repeated during the tightening of the chain. This method has not seemed to conduce, in my experience, to inflammation, and will prove satisfactory, I think, to others who may incline to a trial of it in place of the rapid and continuous process as commonly practised.

J. E. GARRETSON, M.D.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held Wednesday, April 14, 1875, at 8 o'clock P.M.

PRESIDENT, DR. WILLIAM GOODELL, in the chair.

Dr. W. B. ATKINSON read a paper on chloral.

Dr. J. G. STETLER asked Dr. Atkinson whether there are any reliable tests of the purity of chloral. He had seen it stated that a concentrated solution of potassa is a good test. The chloral, if pure, does not color this at all, or, at most, only a feeble yellow, and evolves the pure smell of chloroform. If the liquid assumes a brown color, with the disengagement of pungent odors, it is said to be unfit for use.

It has been stated that it reduces the coagulability of the blood, and tends to its decomposition: if so, we are debarred from its use in certain cases of obstetrics and surgery, attended by hemorrhage. What are its incompatibles? These ought to be known, as it might be dangerous without this knowledge, as we could not know the nature of the products of decomposition.

Dr. ATKINSON, in reply, said that the test mentioned by Dr. Stetler was probably the correct one,—we must depend upon the druggist for the purity. In regard to its effect on the coagulability of the blood, he could not answer. It might be combined with camphor, calabar bean, opium, quinine, etc.

Dr. KEYSER remarked that about two years ago he was called in consultation by Dr. McRean to see a patient of his who had been taking large doses (sixty to eighty grains) of chloral daily for some time, and who had that morning suddenly lost his vision. The pupils were found largely dilated, vision reduced to mere distinguishment of light.

Ophthalmoscopic examination showed great anæmia of the retina only. Supposing it was caused by the chloral, it was discontinued, and in a few days the sight returned to the normal condition.

He had himself taken two doses of ten grains each for extreme wakefulness when suffering from typho-malarial fever, when he sank into a state of alarming prostration, and his attending physician was compelled to desist from its further use.

Dr. McCREAN spoke as follows:

"I have used hydrate of chloral in typhoid fever attended with restlessness and morbid vigilance, also in the same complaint attended with irritability of the air-passages and bowels, with very favorable results. In hysteria and hysterical convulsions, convulsions of children from whatever cause, whether from arterial or nervous excitement, and in infantile colic, it is an excellent remedy; especially in those extreme crying cases of infants it acts like a charm. It also forms a valuable adjunct to cough-mixture.

"I have never observed any bad effects from its administration, either in children or adults. I prescribe it in fifteen-grain doses, repeated at short intervals, from half an hour to two hours, according to urgencies. As a general rule, I prescribe it in wild-cherry syrup. A useful formula for infants is as follows:

"R Hydrat. chloral., gr. xv;
Syrup. pruni virgin., ʒi;
Aquæ menth.,
Aquæ font., aa ʒss.

"Take half a teaspoonful every half-hour.

"I am, however, not strictly bound to these formulas, always taking into consideration the constitution and condition of the patient.

"I consider hydrate of chloral a safe remedy, and prescribe it in cases where I would not dream of prescribing opiates; and shall prescribe it without hesitation in diarrhoea and cholera infantum by the first opportunity. Also in dysentery, in which I have no doubt of its beneficial results.

"I will give you an instance of its prolonged use in a lady patient of mine, aged about 25 years, of exceedingly nervous temperament. I treated her for dyspepsia. She was very melancholy, could not procure any sleep; did not wish to prescribe opiates, for reasons that are obvious: firstly, of producing constipation; and, secondly, to avoid further prostration and disorder of the stomach. I prescribed the hydrate of chloral in fifteen-grain doses (sometimes the dose would have to be repeated) every night, with the desired effect; patient improved, and was soon after discharged. In about a year afterwards I was called in again to see her for a little trifling indisposition, when we had a talk over her former troubles, and she told me, to my surprise, that she had taken the chloral ever since, every night; that she had imagined she could not sleep without it, and that she always arose in the morning refreshed, and with a good appetite. I charged her, however, to discontinue by diminishing the dose every night, and finally stop it, which she did without the slightest inconvenience.

"In conclusion, I will give you my observation and opinion of its *modus operandi*. It is antispasmodic, soporific, and anodyne, allaying erethism, and establishing an equilibrium of action in the system in general: hence it is a safe remedy in all conditions of the system whenever any of this class of remedies is called for."

Dr. BURPEE uses it in typhoid fever, five grains (chloral) every half-hour. One dose often is sufficient, sometimes two are required; but he has never had to use more than three doses to produce the desired effect.

Dr. LEE thought that the subject of chronic chloralism was one of great importance. The remedy is so well adapted to the treatment of hysteroidal cases that there is great danger of its abuse by the patient, and it is, therefore, well to be on the look-out for cautionary signals which may put us on our guard when it is being

pushed, perhaps without our knowledge, to a dangerous extent. The symptom alluded to, of impaired and distorted vision, was a significant one. He had observed it in a case which had been a very instructive one to him from the long-continued persistence in the use of the remedy. The case was one of spinal irritation, so called, complicated with severe lateral curvature, in an unmarried lady. He had exhibited five grains of chloral in her case the night before starting on a voyage to a Southern port. This was a portion of the first specimen imported by Messrs. Wyeth. Its effects were so happy that he authorized her continuance of it, under careful restrictions. It enabled her to get through the voyage in comparative comfort; and the relief which it gave her was so great that she ventured to give the same dose to other persons suffering from painful affections in the house where she was passing the winter, and was thus the means of introducing chloral into Florida.

Being at a distance, and being compelled to rely upon her own observation, she found, after a time, that its uninterrupted use produced smarting of the conjunctivæ, a symptom which was relieved by its suspension for a few days.

On watching her closely after her return, he was able frequently to verify this fact, and also further noticed that it was sometimes accompanied by a diminished power of vision. Another symptom which he afterwards detected, and which appeared to him to indicate a more serious degree of toxic action, usually coming on after using the remedy in fuller doses than usual for several consecutive days, was an excessive aching pain in both wrists. This he had been inclined to look upon as a sign of its depressing action on the heart and arterial system. She has probably averaged about ten grains per diem for the past four years, scarcely ever carrying it above thirty, and often omitting it for a week at a time.

Dr. WITTIG said other sedative and soporific remedies are generally distinguished into such as may be given in inflammatory diseases, as, for instance, hyoscyamus, conium, prussic acid, and such as are contra-indicated by inflammation, as, for instance, opium and its alkaloids, promoting its termination in plastic effusion, by the increase of vascular orgasm which they produce. The lecturer seems to have taken no notice of this distinction, since he does not state whether the cases of mania-a-potu and puerperal convulsions, in which he successfully employed chloral hydrate, were owing to, or associated with, inflammation. He has given hydrate of chloral but once in a case of probable puerperal mania; the uterine secretions emitting entirely the peculiar odor of lochia. He used it in fifteen-grain doses at first, and afterwards in twenty grains; however, two drachms of it produced a mere rest for one hour. The patient was then taken to the insane hospital, where she has since recovered.

Dr. WOODBURY, in regard to the vehicle, said he had found peppermint-water the best to cover the pungent taste of the drug. Although the alkalies were stated to be incompatible, the bicarbonate of sodium is not; but, on the contrary, had been recommended to be added to increase the effect of the chloral (Haynes, *Chloral in Phthisis*, *American Journal of the Medical Sciences*, October, 1874).

Mr. SHINN said that the crystalline form was probably the best test of purity. To his knowledge, a child had recently taken thirty grains in a mistake, without bad results. Also, a lady had been taking five grains on retiring, during a period of three years, without injury.

Mr. REMINGTON had seen some of the first specimens, and was satisfied that a great deal of the difficulty in its use has been occasioned by an impure article. Dr. Squibb is the only manufacturer in this country. The

German article was of an irritating character; corks were eaten and the hands were irritated by it. The markets are now supplied with a purer article. It is deliquescent, and this may account for the irregularity of its action on the system. It can be readily obtained of a uniform quality, if physicians will take the precaution to mark their prescriptions "recrystallized."

Dr. W. W. KEEN alluded to the impossibility of administering it to some persons, on account of the delirium produced. Its prolonged use did not, in his experience, establish a chloral habit analogous to that of opium, nor did the dose have to be sensibly increased.

Its use in anatomy was a very important improvement over other agents now in use. Its cost, even if the best chloral were used (injecting, say one-fourth of a pound, dissolved in six or seven pints of water), was far less than in using other agents, and a damaged article could be had for one dollar per pound, which answered perfectly well. The advantages were that the color was perfectly retained, there was no odor, and if essential oils be used the subject could be rendered even attractive. The tissues were not hardened at all, nor were they softened, unless too much water were used. In fact, everything about the subject has a *living* appearance.

The pathological uses were even more important, as they are more widely needed. Specimens which he had in solutions of five to forty grains to the ounce, after eighteen months were perfectly satisfactory. It renders every specimen accessible at all times, since the jars need not be hermetically sealed, but simply covered or corked, and if evaporation took place to any extent, water alone was needed. The cost was far less than alcohol.

In surgery, as a stimulant and disinfectant (gr. x to $\text{f}\frac{3}{4}$), it still in most cases answered admirably; removing fetor, diminishing discharge, and aiding the growth of the granulations. Especially was it useful in preserving urine, both in cases of incontinence and the like, and for microscopical examinations. In saccharine urine it did not answer.

REVIEWS AND BOOK NOTICES.

ZIEMSEN'S CYCLOPÆDIA. Vol. III. CHRONIC INFECTIOUS DISEASES. Wm. Wood & Co., 1875.

The volumes of this great work appear to follow one another with sufficient rapidity and quickness to warrant the expectation that the work will be completed ere the first portions become stale with age. The most important part of the present volume is the section of syphilis, which is at the same time concise and full, and offers on the whole the best treatise of its size that we are acquainted with. Written by Prof. Baumber, of Freiburg, it has been translated by Drs. Bronson and Ashbridge, with some advantage, as regards the quality of the English, in favor of the latter. The remainder of the volume is occupied with the discussion of diseases derived from the lower animals,—glanders, anthrax (malignant pustule), hydrophobia, foot- and mouth-disease, bites and stings from snakes and other venomous animals, echinococci, cysticerci, and trichinæ. In each case an elaborate account of the natural history of the affection in the lower animals is detailed before its effects upon man are noted. A great deal of information is given which we would not know where else to look for in the English language, so that the volume seems to us even more valuable than its predecessors, although so much space is occupied with a discussion of diseases rare in this country. It has often seemed to us that it was often more important to be well read in rare

than in common diseases. Like the poor, these ordinary affections are with us always, and their features must grow familiar; but to be able to recognize at once a rare although very fatal disease may be to save the life of a patient.

GLEANINGS FROM OUR EXCHANGES.

ANEURISM OF CAROTID ARTERY MISTAKEN FOR ANEURISM OF THE ARCH OF THE AORTA (*New York Medical Journal*, July, 1875).—Dr. W. H. Draper reports the case of a man, 36 years of age, and a hard worker. Ten months ago he noticed a lump in the neck, which pulsed. Six months ago the voice changed in character, and he complained of a sensation of pressure over the trachea. Recently the tumor increased considerably in size, and there was developed a loud aneurismal bruit extending down to the nipple. The heart was dislocated to the left, the apex-beat being found five inches to the left of its normal position. The diagnosis at that time was made of aneurism of the arch of the aorta. The patient grew steadily worse, became œdematous, and then markedly cyanotic, and died.

At the autopsy, an aneurism was found near the bifurcation of the carotid artery, of about the size of a walnut. The sac was filled with fibrine to a degree sufficient to make it nearly impervious. The right pleura contained an effusion. The main affection, however, was valvular disease, with hypertrophy, of the heart, which was displaced downward and to the left, the apex being in the seventh intercostal space. The aorta was slightly dilated, but only sufficiently to be appreciable.

SUBSTITUTE FOR THE ELASTIC STOCKING (*New York Medical Journal*, June, 1875).—To a limb requiring support, a well-fitting bandage is applied, over which, and on either side, a coat of well-made and strained starch is added. Then pasteboard softened in liquid starch is applied, leaving a line of unstiffened material front and back. Over this is added a bandage, which, in turn, is secured by paste. The limb is now suffered to lie quiet until the apparatus hardens.

To remove the hardened bandage, cut along the unstiffened seams, and dress them, bookbinder fashion, with strips of pasted muslin. Cover the inside with pasted strips to prevent creasing. In this way, and in two parts, a perfect case is made for a diseased limb, which may be removed and re-applied with little trouble, and by almost anybody, as often as necessary. The case is kept free from impurities, smell, etc., by sponging on the inside with a solution of carbolic acid ($\frac{3}{4}$ to a quart of water). It is kept clean by first applying an ordinary bandage to the limb, and securing it by the ordinary roller.

OVARIOTOMY (*Atlanta Medical and Surgical Journal*, June, 1875).—Dr. A. Couvert, who has lived on a large farm for some years, and who seems to have successfully combined his agricultural and professional pursuits, asserts that the following points are well established by experience: 1. Effused blood into the cavity of the abdomen does no harm—to a hog. 2. The hog, when cut through the thick muscles of the side, suffers less and recovers sooner than when cut through the thinner but tendinous median line. Many die when thus cut; rarely one dies when cut in the side. This may be due, in part, to the tissues involved, and partly to the weight of the viscera straining the sutures, in one case thus opening the wound, and in the other keeping the lips in apposition, almost without the need of a stitch. Usually the incision in the median line requires three sutures; the side but one.

A CASE OF DOUBLE HERNIA ON THE SAME SIDE (*The New York Medical Journal*, July, 1875).—Dr. James S. Green reports an unusual case, the interest of which consists in the existence on the same side of two hernias, both of which were strangulated: one an *oblique* inguinal rupture of long standing, in which the intestine was adherent to the sac, and which was relieved by taxis at the commencement of the patient's illness; and the other a *direct* inguinal hernia of recent origin, which was undiscoverable until after an explorative operation was attempted, and which was the real seat of the patient's danger.

Another point of interest was, that the tumor of the old oblique hernia could be reproduced by pressure upon the abdomen above the internal ring, and that the swelling immediately disappeared upon the removal of the hand, the flatus filling the intestine returning into the abdominal cavity, showing that the stricture had been removed by taxis, but that the intestine was adherent to the sac.

THE VOMITING OF PREGNANCY (*The American Medical Weekly*, June 19, 1875).—Dr. Copeman, of Norwich, gives his experience of the vomiting of pregnancy. Of drugs, he has found calumba and oxalate of cerium most useful, but these, like all other drugs, sometimes fail. In this case, he recommends dilating the os uteri with the finger, a method which he discovered by accident in the following case. A lady, six months pregnant, suffered from very exhausting sickness, and it was thought necessary to induce premature labor. Dr. Copeman dilated the os uteri with his finger, but, not having any proper instrument, he did not succeed in rupturing the membrane. The sickness, however, ceased, the patient went to the full period, was delivered of a healthy child, and made a good recovery. He has adopted the same method since at the second month, and in the eighth month with perfect success. In these cases he has found the external os puckered, and takes care to make it smooth as well as to dilate it.

AN EASY METHOD OF REPLACING THE RETROVERTED GRAVID UTERUS (*Kansas City Medical Journal*, June, 1875).—Dr. S. N. Denham gives the following directions for replacing quickly and safely a retroverted gravid uterus: "First, empty the bladder; second, place the patient in the position described for using Sims's speculum, or on the back with the knees drawn up (the former is preferable); third, introduce into the vagina an india-rubber bag, or a bladder, with syringe attached so it can be filled with water; fourth, fill the bag with tepid water until some pressure of the perineum is complained of, or the uterus has been discovered, by the hand placed on the abdomen, to have assumed its proper position; fifth, empty the bag or bladder and remove the same. Repeat the operation if the first is not successful, increasing the pressure until the desired effect has been produced."

DANGEROUS COMPOUND (*Lancet*, June 19, 1875).—The *Pharmaceutical Journal* of Vienna states that the following prescription was sent to a pharmacist:—Chromic acid, eight grains; glycerin, one drachm. External use. The dispenser dissolved the acid with a little water in a phial by a little shaking; the glycerin was then poured in, and the phial again shaken. Thereupon the compound exploded with a very loud report, and was carried with great force to the ceiling of the shop. The phial, which did not break, became coated with a black pigment, and remained in the hand of the frightened dispenser. The case deserves attention from the fact that the ingredients were in such small quantities and the explosion so powerful.

STRYCHNIA AS AN ANTIDOTE TO ALCOHOLISM.—Dr. H. C. Morey (*Pacific Medical Journal*) reports the

case of a man who takes large quantities of strychnia to remove the effects of a long-continued debauch. The amount taken corresponds with the length of time he had been drinking and the amount of whisky consumed. On one occasion, when threatened with an immediate attack of delirium tremens, a dose of twenty grains of strychnia restored him to soberness in an hour. For fourteen years the case had been under the doctor's observation. The man was often drunk, and as often rendered sober by strychnia.—*Detroit Review of Medicine and Pharmacy*.

DR. CLAPHAM asserts (*Western Lancet*, June), as the result of an experience of one hundred and twenty-four cases, that nitrite of amyl is an almost infallible cure for sea-sickness. He allows the subject to vomit once, and then exhibits three drops rapidly by inhalation so as to make a decided impression. He has never known a return of the sickness.

DR. A. W. GERRARD (*Pharm. Journal and Trans.*) believes that he has found an alkaloid in jaborandi, and gives the name of *pilocarpine* to it.

MISCELLANY.

TRUE HOMŒOPATHY.—In a report of clinical cases by Dr. L. W. Berridge, *American Journal of Homœopathic Materia Medica*, January, 1875, the following appears:

"Case V.—Mr. — for four years has had pedunculated wart on left neck; for last few days it has become red around and increased in size; smarts at times; when touched it pricks and is very tender. *Lycopod.* 2000 (Boëricke) one dose; wart fell off during next night, to his great astonishment, and was quite well in the morning."—*St. Louis Clin. Record*.

AN OLD FRIEND IN A NEW ROLE.—A Cincinnati genius has discovered that "if nice fat bedbugs are placed in a saturated solution of nitrate of potash in water, and exposed to the air for several days in an open vessel, a very delicate and delicious odor is formed."

AMONG the many mottoes that decorated the Tabernacle on the last anniversary of the advent of the Mormons into Utah was, "Utah's Best Crop—Children."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 13, 1875, TO JULY 19, 1875, INCLUSIVE.

FRYER, B. E., SURGEON.—Relieved from duty at Fort Wadsworth, New York Harbor. S. O. 135, Military Division of the Atlantic, July 10, 1875.

COWDREY, S. G., ASSISTANT-SURGEON.—Granted leave of absence for four months. S. O. 139, A. G. O., July 12, 1875.

AINSWORTH, F. C., ASSISTANT-SURGEON.—Relieved from duty at the United States Military Academy, West Point, New York, and to report by letter to the Surgeon-General. S. O. 141, A. G. O., July 13, 1875.

PORTER, JOS. Y., ASSISTANT-SURGEON.—Assigned to duty with troops temporarily encamped at Indian Key, Florida. S. O. 127, Department of the Gulf, July 13, 1875.

ORIGINAL COMMUNICATIONS.

PHYSIOLOGICAL ACTION OF GELSEMIA.

BY J. OTT, M.D.,

Demonstrator of Physiology, University of Pennsylvania.

GELSEMIA was first procured in a pure state by Prof. Wormley. Mr. Henry Kollock, C. L. Eberle, and Prof. Maisch also obtained it, but in an impure state. The alkaloid is always found combined with an acid called gelseminic. As an average of several experiments, Prof. Wormley states that there are about 3.20 grains of gelsemia in eight fluidounces of Tilden's fluid extract. Wormley said one-tenth of a grain of chloride of gelsemia given by the mouth in a cat caused frothing, in twenty minutes great weakness of extremities, walking with much uncertainty; in forty minutes extreme prostration, entire inability to walk, plaintive cries. Six hours after taking the poison the animal was comparatively well, although the gait was uncertain. Three days afterwards, in the same cat, one-eighth of a grain of gelsemia in shape of chloride caused in fifteen minutes great distress, moaning; in forty minutes great prostration, great difficulty in moving, the legs giving way; progression being as often backwards as forwards; pulse 230, very feeble; respiration gasping, greatly reduced; pupils dilated to fullest extent. Death in an hour and a half after taking the poison, without convulsions.

Bartholow* experimented with an aqueous extract of gelseminum and a little gelsemia obtained from Wormley.

He concludes that in cold-blooded animals it acts on the nerve-centres, paralyzing the sensory ganglia, and afterwards the motor; that it does not affect muscular irritability of the peripheral nerve-fibres. In warm-blooded animals the same effects were observed, save only that the motor centres were the first attacked, instead of the sensory; that it kills through the respiratory apparatus; that in a pigeon it reduced the temperature from 107° F. to 104° F., and in a kitten from 102° F. to 98° F.; that there is no antagonism between it and strychnia; that it dilates the pupil. My gelsemia was made by Messrs. Hance Bros. & White, of Philadelphia. It was yellowish, odorless, with a bitter taste; concentrated sulphuric acid added to a small quantity of it produced a reddish solution, which when moderately heated passed into a fine purple, and nitric acid gave with it a greenish color. It undoubtedly contained some resin. The solution that I used was neutral, and each cubic centimetre contained one centigramme of gelsemia dissolved by acetic acid. On account of the small quantity of the alkaloid in my hands, I also made some experiments with Tilden's fluid extract, a concentrated tincture repre-

senting in each fluidounce four hundred and eighty grains of the root.

ACTION ON THE NERVOUS SYSTEM.

Exp. I.—Very large frog, received at 8.23 A.M. .02 gramme of gelsemia subcutaneously; remains quiet. 8.35 A.M., has a crouching attitude, sensibility much diminished. 8.50 A.M., .04 gramme subcutaneously. 9.35 A.M., .02 gramme subcutaneously. 9.50 A.M., the lower jaw is commencing gradually to relax; moves about occasionally. 10 A.M., croaks and struggles some, suddenly turns himself on his back, in a state of convulsive movements; sensibility exaggerated; twitching of muscles of the extremities for a few minutes. 10.22 A.M., sensibility nearly lost, although movement retained. 10.35 A.M., animal dead. The peripheral end of sciatic irritable at forty-two centimetres Dubois coil; the gastrocnemius directly irritable at twenty-nine. Section of cord gives a slight twitch in extremities.

Exp. II.—Very large frog, received at 11.7 A.M. .06 gramme of gelsemia subcutaneously. 11.24 A.M., sensibility diminished. 12.20 P.M., sensibility very little; upon pinching makes vigorous movements; lies with extremities extended; muscles of lower jaw relaxing. 12.45 P.M., .02 gramme subcutaneously. 1.40 P.M., makes forcible movements of extension with posterior extremities; sensibility very small. 2.10 P.M., .02 gramme subcutaneously. 2.45 P.M., frog dead. Peripheral end of sciatic irritable at twenty-nine centimetres; muscles directly irritable at seventeen centimetres; spinal cord non-excitable; heart beating twenty times per minute.

The above experiments show that gelsemia produces loss of sensibility, want of co-ordination and paralysis of motor power, and finally death. The loss of sensation always precedes that of motion.

Exp. III.—Frog with right iliac artery and vein tied, received at 8.35 A.M. .04 gramme of gelsemia; hops away. 8.50 A.M., sensibility much diminished; 8.54 A.M., .02 gramme subcutaneously. 9.35 A.M., .02 gramme; sensibility greatly reduced; lower jaw hanging down; lies with extremities stretched out; loss of co-ordination. 10.5 A.M., suddenly struggles with posterior extremities. 10.22 A.M., sensibility nearly lost; can move when pinched. 10.23 A.M., dead. Peripheral end of sciatic on poisoned side is excitable at thirty-seven centimetres; on normal side at forty-three centimetres; no reflex action by irritating central end of sciatic; thrusting probe down the spine gives a few feeble twitches; the gastrocnemius on sound side by direct irritation responds at twenty-eight centimetres; the gastrocnemius of poisoned side is excitable at same distance of secondary coil from the primary.

This experiment shows that the poison attacks the sensory ganglia first, and then gradually paralyzes the motor ganglia; that it has no action on the muscular system.

Exp. IV.—Rabbit; at 4.25 P.M. received .01 gramme gelsemia per jugular. 4.27 P.M. to 4.31 P.M., .04 gramme gelsemia. After each injection there were convulsive movements. 4.33 P.M., the rabbit seems unable to move; feet slide from under him; muscles of neck seem especially weak, as head falls down on floor; rolls over on side occasionally. 4.40 P.M., convulsive movements of the fore extremities and muscles of lower jaw; the jaws snap together; violent expiratory movement, accompanied with a crying noise; pupil dilated. 4.41 P.M., animal dead; cord gives a few very feeble twitches on probe-thrust; motor nerves excitable; heart beating.

* Practitioner, October, 1870.

Exp. V.—Pigeon; at 12.35 P.M., received subcutaneously 2.5 cubic centimetres of Tilden's fluid extract of gelsemium. At first he walks off with a slight limp in the leg which received the poison; closes his eyelids frequently; remains stationary, with commencing ruffling of feathers. 12.40 P.M., sits down. 12.42 P.M., vomiting of food; the closing of eyes is less frequent; has a reeling walk. 12.55, respirations nine to twelve per minute. 1 P.M., eyelids nearly closed; feels and hears; staggers greatly; raises head with difficulty. 1.30 P.M., flapping of wings and great agitation, and then death ensues; spine not excitable; muscles are. When poles are placed over eye, the pupil contracts, and when removed it rebounds; no lesion discoverable.

Exp. VI.—3.10 P.M., rabbit received subcutaneously four cubic centimetres of fluid extract of gelsemium. 3.15 P.M., the extremities of feet lose their power, although the animal manages to locomote. 3.40 P.M., rolls backward on long axis; moves about; great difficulty in expiratory act; pupils dilated. 4.5 P.M., death. Right side of heart filled with blood; left side flaccid, and nearly empty; heart beating feebly.

The above experiments show that gelsemia is a respiratory poison; that it attacks the motor ganglia, and finally the sensory, reversing the order as compared with cold-blooded animals.

EFFECT ON THE CIRCULATION.

That the method of experimentation may be better understood, I give a short résumé of cardiac physiology as taught at present.

The heart contains ganglia which send motor fibres to the cardiac muscle. In addition to motor ganglia there are other ganglia, called regulating ganglia, which co-ordinate the action of the heart, and act on the muscular fibres of the heart through the motor ganglia. The regulating ganglia oppose a certain resistance to the transmission of motor impulses to the cardiac muscle,—that is, governing the rhythm, and preventing the motor ganglia from exhausting themselves by irregular and excited action. Although the heart contains its own power of action, yet there are afferent and efferent nerves which play an important part in its movements: the pneumogastrics when irritated slow the pulse and augment its force, whilst the accelerators increase their number, but diminish their power. The pneumogastrics are especially excited by carbotic acid, decrement of temperature, and the sad emotions, whilst the accelerators are particularly thrown into action by the exhilarating emotions, increment of temperature, and oxygen. The brain also takes part in the regulation of the circulation through the vaso-motor centre situated in the medulla. This centre regulates the calibre of the small arteries, diminishing or increasing the amount of blood flowing through them. The cardiac afferent nerves just described can be thrown into increased action by sensations through the terminations of the sensory nerves in any section of the body: hence the irritation of any portion of our skin can modify the amount of blood which flows through our body in a certain time, thus altering by necessity the functions of other organs. This fact explains the action of many external remedial agents, as baths, sinapisms, actual cautery, etc. The

afferent nerve-fibres of the heart are the depressors of Ludwig and Cyon; they are the mechanism by which rupture of the heart by great arterial tension is avoided; as an excited action of the vaso-motor centre might cause. They convey the impulse from the heart to the vaso-motor centre which is paralyzed, and thus the small arteries are relaxed and the heart empties itself, the tension decreases, and everything works freely; they are the safety-valves of the heart, similar in function to those found on steam-engines. These nerves also convey to the brain the sensations of a light, heavy, or palpitating heart.

In a pamphlet* published some time ago, I recorded some experiments on the circulation with an aqueous extract of gelsemium. As there were many other organic and inorganic bodies necessarily introduced with the gelseminate of gelsemia, the observations can only be of value as confirmatory of the action of the alkaloid. In the main they support the conclusions drawn from the following experiments. The circulation as influenced by this poison was studied on rabbits benumbed by sulphate of morphia, both in the interests of humanity and the experiment itself. The pulse and pressure were noted by Ludwig's mercurial manometer on the drum of his registering apparatus. The rate of movement was marked on the drum by an electro-magnet every second. By a lever attached to the electro-magnet the beginning and end of each injection were registered, as well as the time during which a nerve was irritated. The instruments used for irritation were one Grove cell eighty-one millimetres high and fifty-eight millimetres in diameter, Dubois-Reymond's induction apparatus, and Ludwig's electrodes. As the poison caused convulsive movements, curare was used to eliminate the action of the muscular system on the circulation. The gelsemia was injected towards the heart through the jugular or one of its branches, no air being allowed to enter; artificial respiration similar to normal was kept up, by an apparatus on the principle of Sprengel's blower, at regular intervals, by an electro-magnet and metronome; the carotid artery was used for kymographic observations. The blood-pressure is given in millimetres of mercury, and the pulsations for periods of fifteen seconds.

Exp. I.—Rabbit; tracheotomy; jugular and carotid prepared; curare; artificial respiration.

6.3.45	44	26
6.5.00	48	24
6.6.15	46	25

The above experiments demonstrate that in gelsemia we have an agent which reduces the pulse and pressure, the latter greatly.

Now, physiologically, the pneumogastrics either by central or peripheral stimulation have the ability to reduce the pulse.

The pressure can be reduced by diminished tonus of the vaso-motor system or weakened heart.

That I might find out if gelsemia reduced the pulse-frequency by central stimulation of the pneumogastrics, they have been divided in the following experiment:

Exp. III.—Rabbit. Tracheotomy; carotid and jugular prepared; vagi cut; curare; artificial respiration.

TIME.	PULSE.	PRESSURE.
A.M.	51	92
		Gelsemia .01 gramme.

11.36.45	52	68
11.37.15	48	46
11.37.45	46	40
11.38.30	44	28
11.39.45	32	22
11.46.15	38	18
11.54.45	39	20
11.55.00	33	16
		Vagus irritated with Dubois secondary coil at 1 for six seconds; one Grove cell.
11.56.00	37	26
12.00.15	40	36
		Vaso-motor centre irritated indirectly with Dubois coil at 1 for fourteen seconds.

The same sequence of events takes place, so that gelsemia does not reduce the pulse through central stimulation of the pneumogastrics. In atropia we have an agent which is capable of removing the inhibitory power of the peripheral end of the vagi on the heart.

The succeeding experiment shows that even after paralysis of the inhibitory ganglia seated in the heart, gelsemia produces the same result.

Exp. IV.—Rabbit. Tracheotomy; vagi paralyzed by atropin, as tested by strong currents; curare; artificial respiration.

To study the action of a poison on the heart itself, it is necessary to divide the afferent and efferent cardiac nerves in the neck (that is, the pneumogastrics, sympathetics, and depressors), and to remove the influence of accelerators and vaso-motor centre by section of the cord between the occiput and the atlas. In this manner the following experiment was performed:

Exp. V.—Rabbit. Tracheotomy; all the cardiac nerves in the neck cut; the cord divided between the atlas and occiput; the hemorrhage checked by bovista; curare; artificial respiration; section of cord verified by post-mortem.

TIME.	PULSE.	PRESSURE.
A.M.		
11.34.00	43	18
		Gelsemia .01 gramme.
11.54.45	43	15

11.37.00	37	15
11.38.00	37	15
11.40.00	36	16
11.41.00	37	16
11.41.25	36	16
		Gelsemia .01 gramme.
11.41.35	35	14
11.42.35	34	13
11.43.35	36	14
11.44.35	34	13

This experiment demonstrates that the cause of the slowing of the pulse resides in the heart itself, as well as part of the reduced pressure. Although the fall of pressure is partly to be explained by decrease of cardiac irritability, yet it is desirable to prove how far the vaso-motor nerves and the muscles in the arterial walls participate. When in the small blood-vessels the circular muscles relax, thus dilating the vessel, there is less blood flowing into the right ventricle, and consequently less into the left ventricle, which, by necessity, throws less blood into the arterial system than before in the same unit of time; consequently this is one factor of diminished pressure.

When the small arteries are dilated there is less resistance to the onward flow of blood, and, of course, less pressure in the arterial system, which is another factor.

When the pressure is diminished, according to the German school, the pulse is lessened. The grand agent in preserving the arterial pressure at its height is the vaso-motor centre. That the vaso-motor centre is not paralyzed to direct irritation the following experiment proves; but there is a probability that its tonus is lowered as the fall of pressure is greater, and more rapid when the centre is active than when its influence is removed.

Exp. VI.—Rabbit. Vagi paralyzed by atropin; tracheotomy; sciatic nerve prepared; Ludwig's gimlet-electrodes screwed into the atlas and occipital bone; Pohl's commutator used, so that the induced current could be sent either to the gimlet-electrodes or the electrodes bearing the sciatic by simply rolling the cradle.

TIME. A.M.	PULSE.	PRESSURE.	
	55	80	
			Gelsemia .01 gramme.
10.35.15	53	70	
10.35.45	52	78	Vaso-motor centre irritated directly for two seconds; secondary coil at 8.
10.38.24	52	50	
			Gelsemia .01 gramme.
10.38.39	51	31	
10.38.54	47	18	
10.39.19	52	18	
10.39.34	53	72	
10.54.11	43	5	
10.54.26	42	3	Depressor nerve irritated eight seconds; Dubois coil at 8.
10.58.30	48	8	
11.06.45	46	22	Vaso-motor centre irritated directly for eight seconds; Dubois coil at 8.

The deductions from the above experiments are:

1. That gelsemia reduces the pulse and the pressure; the latter greatly.
2. That the pneumogastriacs are not affected by it.
3. That it reduces the pulse by an action on the heart itself, probably through a paralyzing action on the excito-motor ganglia.
4. That it reduces the pressure through diminished cardiac irritability and decreased vaso-motor tonus.
5. That the functions of the depressor are not interfered with.

ACTION ON THE RESPIRATION.

Exp. I.—Rabbit. T-shaped tube in trachea; jugular prepared; Marey's polygraph registering respiration on Ludwig's drum; the rapidity of the movement of drum being noted by an electro-magnet, marking seconds.

TIME.	RESP. FOR 15".	
	16	
		Gelsemia .01 gramme.
4.34.00	19	Struggle, convulsive movement.
4.34.15	16	
4.34.30	12	
4.34.45	12	
4.35.15	11	
4.36.45	11	
4.37.00	11	
4.40.15	11	
4.53.21	11	
5.01.40	11	
		.005 gramme gelsemia.
5.01.55	11	
5.02.55	10	Convulsive movements.
5.03.35	11	
5.05.15	9	Opisthotonos.
		Gelsemia .01 gramme injected.
5.05.30	12	
5.05.45	11	
5.08.00	7	
5.14.00	6	
5.25.15	1	

The above observation shows that gelsemia gradually reduces the number of respirations. The paralyzing effect on the respiratory centres is the cause of this action, as the poison does not attack either the pneumogastriacs, the striated muscles, or the motor nerves.

ACTION ON THE TEMPERATURE.

The following experiment was made with a specimen of gelsemia furnished by Charles McIntire, Jr., formerly Assistant Professor in Lafayette College. The temperature is rectal.

Exp. I.—2 P.M., kitten received subcutaneously .004 gramme of gelsemia in shape of chloride. 2.05 P.M., weakness in posterior extremities; trembling of head and ears; pupil in diameter five millimetres; temperature $101\frac{3}{10}^{\circ}$ Fahr. 2.25 P.M., .002 gramme gelsemia. 2.37 P.M., sinking down on fore-legs, drooping of head, difficult expiration. 2.45 P.M., temperature $101\frac{8}{10}^{\circ}$, pupils same. 2.50 P.M., cries, makes staggering efforts to walk, but sinks into a prone position; backward movements; no co-ordinating power; sphincters give way. 3.40 P.M., .004 gramme gelsemia. 3.55 P.M., temperature $100\frac{3}{10}^{\circ}$; pupil five millimetres. 4.25 P.M., .004 gramme. 4.56 P.M., pupil six millimetres; .002 gramme gelsemia; temperature $99\frac{1}{10}^{\circ}$. 5.5 P.M., pupil seven millimetres; reflex movement in cornea. 5.10 P.M., .004 gramme gelsemia; death; chest opened; auricles beating, but not ventricles; intestinal peristalsis present; cord not excitable; muscular irritability good; no reflex action; heart excitable when electricity applied.

Exp. II.—Rabbit. Temperature $103\frac{3}{5}^{\circ}$ per rectum. 8.40 A.M., received subcutaneously $2\frac{1}{2}$ cubic centimetres of fluid extract of gelsemium. 8.45 A.M., temperature $103\frac{3}{5}^{\circ}$. 8.52 A.M., four cubic centimetres fluid extract gelsemia. 9 A.M., temperature $103\frac{3}{5}^{\circ}$. 9.12 A.M., temperature $102\frac{2}{5}^{\circ}$. 9.45 A.M., temperature $101\frac{1}{5}^{\circ}$. 10.20 A.M., injection four cubic centimetres fluid extract gelsemium. 10.30 A.M., temperature 99° . 11 A.M., $98\frac{3}{4}^{\circ}$. 11.5 A.M., animal dead.

These experiments show that gelsemia reduces the temperature.

To make more complete and practical the study of the action of gelsemia, I give the following experiments on man,—cases of poisoning. Substantially they are as follows:

Case I.—Reported by R. P. Davis. Lying on left side; muscular relaxation; face somewhat congested; double vision; vertigo; pupils dilated, but responding to different degrees of light; eyelids half closed, with apparent inability to move them; lower jaw drooping; his tongue, to use his own expression, "so thick that he could hardly speak;" skin warm and moist; pulse small and feeble; neither purging nor vomiting; respirations diminished; great numbness of the extremities; surface cold and congested; pulse almost imperceptible. Death took place in about two hours and a half after taking a tablespoonful of Tilden's fluid extract; unconsciousness preceding death for an hour.

Case II.—Reported by R. P. Davis. After same dose, double vision, vertigo, pupil widely dilated, complained of blindness, staggered in walking, deep inspirations, and numbness of whole body; no loss of consciousness at any time; awoke next morning weak and dizzy. The patient in the first case was a

very small, nervous, delicate man; the second case was the reverse, and, besides, he received an emetic soon after taking the poison.

Case III.—Prof. Wormley reports the following case: Young married woman, pregnant, took three teaspoonfuls of Tilden's fluid extract. In two hours complained of pain in stomach, nausea, and dimness of vision. These symptoms were followed by great restlessness, ineffectual efforts to vomit, and free perspiration over the body. At the end of five hours pulse feeble, irregular, and sometimes intermittent; great prostration, irregular and slow respiration; skin dry, extremities cold, pupils expanded and insensible to light; eyes fixed, and inability to raise the eyelids. Death occurred in about seven hours and a half after taking the poison. No convulsions preceding.

Prof. Wormley thinks that these three teaspoonfuls could not have contained more than a sixth of a grain of the alkaloid.

Case IV.—Reported by Dr. Main. He took one drachm of fluid extract of gelsemium. Nearly blind; control over upper eyelids was almost entirely lost; flexor muscles of hands and arms paralyzed; extensors nearly so; sensation in hands and arms blunted, but not in proportion to loss of motion. Before muscles affected, disagreeable sensation in head; mind clear; hands suffered more than the legs.

Case V.—Reported by Dr. Freeman, of Brooklyn. Boy, æt. three years. After taking fifty minims of tincture of gelsemium (made by maceration of four ounces of the root to a pint of dilute alcohol), died in two hours. The symptoms were double vision, staggering gait, complete muscular relaxation.

Case VI.—Reported by Dr. Freeman. Girl, æt. nine years; after dessertspoonful of tincture, had dimness of vision, loss of muscular power, and death in less than two hours.

Case VII.—Reported by Dr. Freeman. Boy, æt. about three years, was to take a teaspoonful every two hours of a mixture containing ten grains of sulphate of quinine, a drachm of tincture of gelsemium, and five drachms of syrup. After first dose, prostration, staggering; in about half an hour after second dose, limp as a rag; pupils dilated, froth, heart beating feebly and slowly, pulse imperceptible at the wrist, could not swallow. Death in about an hour after the second dose.

Case VIII.—Reported by Dr. Pinkham, of Lynn. Double vision, blindness, numbness, oppression, unconsciousness, stertorous, very imperfect breathing, countenance lividly pale, lower jaw drooping, leaving mouth wide open; eyelids partially closed, motionless; pupils moderately dilated; pulse 100 per minute, regular, weak. After friction and stimulus for an hour and a half, consciousness returned, but recovery was not complete for several days, the principal complaint being great prostration, muscular weakness, particularly of the elevators of the lower jaw, eyelids, and muscles of arm. After the return of consciousness, speech was intelligible only when the jaws were supported. The tongue during the poisoning was stiff, and voice guttural. The

dose was pretended to be forty minims of fluid extract, and the patient was a woman.

Case IX.—Reported by Dr. Boutelle, of Boston. Man, æt. twenty-four, at 1 A.M. took a teaspoonful of Tilden's fluid extract of gelsemium. In fifteen minutes he repeated the dose; his pain was soon relieved; eyes felt heavy, and in about half an hour complained of choking; soon arose, struggling for breath, pushing his fingers into his throat as if trying to tear it open. He staggered reeling from one room to the other, as though intoxicated, and shortly afterwards threw himself on the floor, and became unconscious. 4 A.M., respirations gasping, three or four per minute; pulse rapid and feeble; unconscious, could not be roused; pupils dilated, not responding to light; eye could be touched without any contraction of the lids; skin moist; extremities cold; pulse grew slower and weaker. Death in three hours and forty-five minutes after taking the poison, without any convulsions occurring at any time.

An analysis of the above cases of poisoning gives the following as the course of symptoms: Disordered double vision, ptosis, want of co-ordination in the movements, disagreeable feeling in the head, great muscular relaxation, lower jaw drooping, tongue stiff, sensation blunted, pupils dilated, respiration slow and irregular, pulse slow and feeble, surface cold and congested, unconsciousness, and death.

On comparison of its effects on man and warm-blooded animals, the analogy is complete. In man there is the same paralysis of motion, want of co-ordination, diminished sensibility, relaxation of muscles of the jaws and the rest of the body, diminished pulse and pressure, lessened respiration, decreased temperature, and dilated pupils.

The following résumé expresses our conclusions in regard to gelsemia:

1. In cold-blooded animals it paralyzes first the sensory ganglia, and then the motor ganglia in the central nervous system. This order is reversed in warm-blooded animals.
2. It diminishes the pulse and pressure.
3. This decrease of pulse-rate is due to lessened irritability of the excito-motor ganglia of the heart.
4. The fall of pressure is due to diminution of cardiac irritability and vaso-motor tonus.
5. It decreases the respiration through a paralyzing action on the respiratory centres.
6. It dilates the pupils.
7. It reduces the temperature.

The above investigation was made in the Physiological Laboratory of Prof. F. G. Smith, University of Pennsylvania.

OXYGEN IN CONGESTION OF THE BRAIN (*Boston Journal of Chemistry*, July, 1875).—A French physician reports to the Academy a case in which he has succeeded in curing grave congestion of the brain, along with paralysis of the whole right side, by making the patient inhale pure oxygen: from the first inhalation the patient got relief, and motion and sensibility returned by degrees.

A CASE OF CHOREA IN THE NEGRO.

BY W. T. SKINNER, M.D.,

Glasgow, Delaware.

MY attention having been called to the fact, by the inquiries of Dr. S. Weir Mitchell, that chorea in the negro is extremely rare, I deem this sufficient apology for reporting the following case :

May 22, 1875.—D. B., æt. 18, colored (of pure African descent), servant-girl from Philadelphia, has suffered for some time with subacute rheumatism, at the termination of which she was suddenly seized with choreic movements mostly affecting the muscles of the head and neck, characterized by a continual bobbing or shaking of the head. The legs and arms are affected only when she attempts to use them. The movements are all increased by exercise and diminished by rest, and entirely suspended when the patient lies down. The tongue can be thrust out only by some effort. The face is unaffected.

Pulse 144. Slight murmur at the apex, heard most distinctly a little external to the nipple. Menstruation regular. No spinal tenderness or other evidence of hysterical temperament.

I cannot get her family history ; I only learn that she has lost several brothers and sisters, and therefore suppose it is not very favorable.

Her nutrition is bad. She is directed to make use of liberal diet, to take exercise moderately and frequently in the open air ; and, in the way of medicines, cod-liver oil, syrup of iodide of zinc, and tincture of digitalis are ordered.

June 18.—The improvement has been gradual. She now has intervals of rest from the movements, but they are called into operation by any attempt at exercise, such as walking, or even standing. Pulse 80, and regular ; cardiac murmur unchanged. General condition much improved. Same remedies continued, and strychnia, one-twenty-fourth gr. thrice daily, added.

July 14.—Patient still improving ; same treatment continued.

NITRITE OF AMYL IN HYSTERICAL CONVULSIONS, THE COLD STAGE OF INTERMITTENTS, AND CHLOROFORM-NARCOSIS.

BY RUFUS R. HINTON, M.D.

CASE I.—Last February I was called to see Mrs. R., æt. 27 ; she was subject to hysteria, and frequently had convulsions at the time of her monthly sickness. At the time of my visit she had had convulsions at intervals of four or five hours, for four days previous. I found her in a series of subintense convulsions ; the pupils, pulse, and temperature were normal. As the patient had been treated with the bromides, valerian, etc., without relieving the spasms, I concluded to use the nitrite of amyl by inhalation in from three- to five-drop doses ; and in two hours from the time I commenced the treatment with the nitrite of amyl, all symptoms of convulsions were relieved, and the patient has had no convulsions to this date.

I have used the nitrite of amyl in two cases of hysterical convulsions since the one just described : one in a young girl of 16, and one in a married woman suffering with dysmenorrhœa, with like success.

Case II.—A negro man called at my office in the early part of March to be treated for a case of chronic

chills, of the tertian type, which he contracted while working upon the Eastern Shore of Maryland, last fall. As the chill was expected the next morning, I told the patient to go home and send for me on the first symptoms of its coming. When I was called I found the patient with a shaking ague, with ashen hue of skin, feeble pulse, great irritability of the stomach, constant retching. I gave him five drops of nitrite of amyl by inhalation. In a few seconds the ashy hue of the skin disappeared, vomiting ceased, reaction was complete, with very little fever ; in two hours from the time I first saw the patient he was out of bed, and by the liberal use of quinine and iron the patient had no more chills.

Case III.—Capt. H. called at my office to be treated for a whitlow involving the first and second joints of the middle finger. Dreading the operation of laying open the finger with a knife, the captain suggested the use of chloroform, which he had taken for two or three minor operations, while in the army, without any bad result. I sent for 3i of Squibb's chloroform, and, pouring two or three drachms upon his handkerchief, directed him to inhale it, at the same time directing him to elevate his hand, intending, so soon as the hand dropped, to lay open the finger. As the hand dropped, I noticed that the patient was of a deathly pallor, and had ceased breathing ; opening his mouth and drawing the tongue forward with a tenaculum, I immediately applied five drops of the nitrite of amyl to the nose and mouth. To my delight, flushing of the face, with violent beating of the carotids, ensued, and the captain opened his eyes, wanted to know where he was, and consented to have his finger incised without the further use of chloroform.

TRANSLATIONS.

ON THE COMPARATIVE ANTISEPTIC EFFECT OF BENZOIC AND SALICYLIC ACIDS.—Prof. E. Salkowski, of Berlin (*Klin. Wochenschrift*, No. 22, 1875), has been making a series of researches with different disinfectants, and particularly with the two above mentioned. The result was markedly in favor of the benzoic acid, whose antiseptic properties were shown to be decidedly greater than those of salicylic acid. This result is quite opposed to that obtained by Kolbe in his recent but very well known researches. Prof. S. thinks the reason of this lies in the different qualities of benzoic acid used. Benzoic acid obtained from balsam has a quite different odor from that obtained from urine, and may, it is likely, have a different effect.

Whether or not this may be the reason, the fact of the superiority of benzoic to salicylic acid, as well as the superiority in cheapness of the former, renders its thorough trial very desirable.

X.

THE URINE OF NEW-BORN INFANTS (Martin, Rye, and Biedermann: *Centralblatt für Med. Wissenschaften*, No. 24, 1875).—From examinations of the urine of seventeen male children during the first ten days of life, the following conclusions were arrived at :

1. The first discharge of urine is very rarely immediately after birth ; is usually at the end of the first day of life, often not until the second or third.
2. The average quantity of the first evacuation of urine is eight cubic centimetres.
3. During the next ten days the amounts of urine discharged are not constant, varying from twelve to sixty-one cubic centimetres.
4. The color of the fluid on the first day corresponds to Nos. 1 and 2 of Vogel's scale ; on the later days the urine becomes gradually almost as light as water.

5. The reaction is almost always moderately acid; very rarely neutral; for if not acid it has usually a marked tendency to alkalinity.

6. The specific gravity of the first urine averaged 1010.5.

7. The specific gravity during the entire ten days varied from 1002.7 to 1010.0.

8. In the urine of each of the children albumen was noticed upon one or more days.

9. Chlorides were found in all the evacuations.

10. The average amount of urea was 0.321 per cent.

11. Uric acid was constantly present in the first urine, and increased in quantity until the third day, when a diminution took place.

12. Under the microscope, the urine of the first day and that of the following days until the fourth was found to contain epithelium from the urinary tract in large amount, varying quantities of epithelium from the uriferous tubules, and masses of uric acid crystals.

W. A.

LEAD COLIC TREATED BY LARGE ENEMATA OF WATER.—Dr. Reisland gives the following case in the *Berliner Klinische Wochenschrift*, No. 21, 1875. He was called to see a man 50 years of age, whose occupation had exposed him for some years to lead-fumes. The patient had suffered for some weeks from pain in the abdomen, with obstinate constipation, accompanied during the few previous days by occasional vomiting. Enemata of various kinds which had formerly emptied the bowels had latterly failed to give relief; ol. ricini in large doses had also been unavailing. The condition of the patient at the time Dr. R. first saw him was almost that of collapse, with frequent general spasm and muscular contractions, particularly of the arms and legs; accompanied by retching and vomiting of bilious matters. His face was pale, grayish-white in color, a distinct lead line could be seen on the gums, the tongue was foul. The abdomen was hard, tense, and somewhat retracted; pain extending to the small of the back, the testicles, and the thighs. Pulse 65, small. Temperature normal. The patient was ordered the following:

R. Ol. croton., gtt. iii.

Ft. in pil. no. xv.

Sig.—Two every half-hour.

In addition, opium in half-grain doses every two hours. In the afternoon, in spite of having taken all the pills and four doses of opium, no relief had been obtained. It was then decided to use large enemata, and for this purpose an irrigator was made use of which would contain about a litre (two pints), having attached to it a yard of rubber tubing and a nozzle of hard rubber.

The irrigator was filled with lukewarm water, the patient took the knee-elbow position, and the nozzle was introduced a finger's-length into the rectum. When the irrigator was raised, the water passed into the intestine in a continual stream; before the irrigator was empty, more water was added, until four and a half litres had been introduced. The patient complained of severe pain, and the injection was then stopped. A few moments after, a partial stool was obtained; then further enemata were given, and the bowels were thoroughly emptied. This procedure was repeated daily for several days, by which time all pain, etc., had disappeared, and the stools were normal. X.

FOREIGN BODY IN THE RECTUM.—Dr. Greinblatt communicates the following case to the *Wiener Med. Presse*, June 20.

He was consulted by a man who gave the following history. Four days previously he had indulged in an unusually large meal without suffering any immediate evil results. Forty-eight hours later, however, he was seized with pain in the stomach; a day later, difficulty

in urinating and impossibility of defecation ensued, and the symptoms increased until he was forced to seek medical assistance. On examination, the abdominal region was found tense and tympanitic. The upper portion was resonant on percussion, the lower dull. The painful region was evidently in the rectum. Exploration in this locality showed an elongated foreign body lodged transversely in the rectum just above the internal sphincter. This was carefully turned endwise, and removed by the aid of forceps. Upon examination, it was found to be a portion of the rib of a lamb, nearly an inch in length, which had passed the œsophagus, cardia, pylorus, small and great intestine, only to become lodged in the rectum. Immediate relief followed its removal. X.

VERRUCA SENILIS (KERATOSIS PIGMENTOSA).—Under this designation J. Neumann describes (*Wien. Med. Presse*, No. 13, 1875) a skin-affection of old people, characterized by the appearance of numerous wart-like tumors particularly upon the back and breast, varying from rusty brown to deep black in color. The friction of the clothing sometimes produces excoriations and ulcerations in these tumors, which, under such circumstances, cause great annoyance. The tumors are formed by the stratified accumulation of epithelial cells on the smooth surface or upon a papillary base. Microscopically, the accumulated epidermis shows nothing abnormal; the atrophied rete Malpighi in its collections of pigment-cells, as well as the adventitia of the vessels, have become rounded masses, whose contents are formed of horny cells, masses of smegma, and lanugo hairs. The sebaceous glands are enlarged, filled with dried smegma, their openings stopped up or atrophied. They project like warty pale-red growths.

Verruca senilis is distinguished from ordinary verruca in that the epidermoid character is more prominent, the papillæ taking no part in the growth itself, for which reason the name keratosis pigmentosa is suggested. Sapo viridis, pencilling with iodized glycerin or with dilute carbolic acid, may be used to bring about atrophy. A shorter method is the use of "Daniel's spoon."—*Berliner Klin. Wochens.*, No. 21, 1875.

X.

ALEPPO EVIL.—This affection, known under various synonyms, has long been supposed to be a specific affection, localized in the East, and particularly in and about the city from which its name is derived. Recently, however, an enterprising German, Dr. Geber, assistant to Prof. Hebra, established himself in Aleppo, and set up a skin-dispensary chiefly for the purpose of studying this affection. His conclusion (published in the *Vierteljahreschrift f. Derm. u. Syphilis*, 1874, 4tes Heft), after a large experience, is that all the forms of Aleppo evil are simply varieties of syphilis. X.

SALICYLIC ACID IN DIPHTHERITIS.—Dr. Hanow writes to the *Berliner Klin. Wochenschrift*, No. 20, 1875, praising very highly the valuable qualities of this remedy in the above disease. He uses the acid in solution, one part to three hundred, as a gargle, or in the stronger solution which is made by the addition of phosphate of sodium. The gargle is used hourly, and in the cases under Dr. H.'s care relief was obtained very shortly. After the third or fourth dose the membrane began to separate, and with the diminishing of the exudation the fever began to disappear, convalescence setting in after twelve hours. X.

ABLATION OF PEDICULATED TUMORS OF THE SKIN BY THE GALVANO-CAUSTIC.—Amussat (fils) recommends this procedure, having had successful results in seven cases, comprising papilloma, lipoma, fibroma, and condyloma acuminata (*Revue de Thérap. Méd. Chir.*, 1875, Nos. 2 and 3).

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JULY 31, 1875.

EDITORIAL.

WICKER-WORK COFFINS.

ALLUSION has already been made in the columns of this journal to the idea of Mr. Seymour Haden, that the object of coffins should be to facilitate decay, not to retard it. As the law, dust to dust, ashes to ashes, is as unescapable as death itself, as even the highest perfection of the Egyptian art can but protract the return of the body to the great mother, earth, we confess that we sympathize with the belief of Mr. Haden, that it is better to assist than to attempt to defy nature. Leaden coffins, hermetically-sealed caskets, are, after all, but the devices of the undertaker to take advantage of human weaknesses. It is related of an old Scotch stone-cutter, that when asked how it was he always succeeded so well in selling expensive tombstones, he replied, "I talk to them till I see a tear in their eye, and then I strike." Led by undertaker and tombstone-maker, many a widow has expended upon the burial of her shattered hopes money that should have been garnered up for the living. The reform proposed by Mr. Haden is to do away with all temptation to undue expense.

Just here, some of our readers may desire to know who this Mr. Haden is. He is no ordinary man; indeed, according to our thinking, he is a very remarkable man,—a living reprobation of the time-honored but narrow and untrue belief that to be a successful doctor one must be a doctor and nothing else. Mr. Seymour Haden is widely known as a medical practitioner; but the chief glory and, no

doubt, the chief joy of his life is that he is the "most original and accomplished etcher now alive in Great Britain."

The coffins advocated by Mr. Haden are to be of wicker; made with a strong, pliant osier,—a double thread being preferable,—with as wide meshes as is consistent with holding the flowers, ferns, mosses, evergreens, etc., in which the body is to be laid. In order to facilitate the recognition of the bones if it should ever happen to be desirable, an engraved leaden band is to be tied around the wrists, a second around the legs, and a third passed through the chest.

The procedures when death has occurred are as follows:

"As soon after death as may be, the body is to be sponged, the eyes are to be closed, the chin supported, the limbs composed, and the hands crossed upon the breast. Superfluous bedclothes, together with the impediments and rejectments of the sick-room, are to be removed, and a window is to be opened a few inches both at the top and at the bottom. The papers of the deceased may then be examined, and, if these contain nothing to forbid it, the first preparations for the funeral may be made in the following way. As part of the ordinary stock-in-trade of every turner, brush-maker, or basket-maker, will be found, nested one within the other, and of every form and dimensions, the necessary covering or coffin; at every herbalist's or florist's, its garniture. Both, being light and portable, may be delivered at the house in an hour or two, and the body may be at once laid in it and strewn (except the face and hands, which should be left exposed) with its evergreen covering. All this may be done by the nurses or older servants or members of the family, and no stranger need be admitted. There is now ample time to consider arrangements, for the visit of the physician or surgeon charged to verify the fact of death, to telegraph to friends, and to make final preparations for the interment. The morrow come, and everything prepared inside and out, the necessary agents for the interment will enter the house for the first time and the last, and remove the body in a suitable carriage, either by railway or by water, to its resting-place outside the city, one of the male representatives of the family in every case accompanying it. There will be no procession through the streets,—no opportunity for display,—nothing to elicit either the sympathy or the criticism of the neighborhood (both on such an occasion equally out of place); but, arrived at the cemetery, the body will wait in the mortuary chapel attached to it, with those who are to be present at its interment. These, having been informed of the death, will go and return as their desire, affections, or respect for the dead impel them. The assembly will be in the chapel, and at the grave-side only, where the mourners, men and women (for, since there is to be no public display, both may go), will find the trellissed coffin on its bier, garnished and beautified by

loving hands, awaiting them. Not a word of our burial service will be omitted, though more may be said in the chapel and less at the grave-side, and then all will be over. There will be no reunion at the house of death. The conventional feast will not be spread. The formal reading of the will will be at the office of the legal adviser of the family on a day appointed for the purpose; and the inmates of the house of mourning will return to it and be allowed to remain undisturbed. Next day every one will to his business."

The care of Mr. Haden does not stop with the burial. Where there is a deep, loamy soil, with a gravel substratum, natural grave-yards may be employed, but in most large cities he thinks artificial cemeteries are to be preferred. A series of experiments should first be made to determine what form of soil will most facilitate rapid decay. It will probably be found that an earth composed of fine carbon soil, sand, and lime, is the best; but, whatever compound is decided upon, an artificial soil of about twelve feet in depth forms a basis of this model grave-yard.

So far as this country is concerned, the artificial cemetery is certainly an absurdity,—the expense of making it and the comparative cheapness of land being insuperable objections. Mr. Haden's coffins may possibly come into use; certainly his method is better than cremation, in that it is not only less expensive, but is infinitely less repulsive to the overpowering instincts generated in the Anglo-Saxon breast by custom and teaching immemorial.

Indeed, prejudice is so strong, class interests so powerful, that had not Mr. Haden unexpectedly secured the eager aid and patronage of the Duke of Sutherland, his propositions would have been, even for England, as wild beating of the air as have been all the efforts to introduce cremation.

The duke appears to be an enthusiastic amateur philanthropist, and, being placed above absolute want by his inherited estates and by his marriage, has plenty of leisure for whatever he undertakes. Moreover, as he holds by his own right in the county of Sutherland 1,176,343 acres of land, and in the name of his wife 149,879 acres in the adjoining county of Ross, he is not without influence in a country like England, "in which the possession of land gives a factitious importance even to the humblest and poorest possessor such as no amount of stocks and shares and bankers' balances can ever give." On the 17th and 19th of June the duke gave what may be termed coffin receptions at Stafford House. All London was invited, and all London was there,—some to see the duke set in a framework of coffins, some to see Stafford House, some to see the crowd, and a

few to see the coffins. Flirting among the coffins, if not "the ruling passion strong in death," was something akin thereto. Altogether, we conceive that West End London has had a new sensation, which certainly is a thing for which many *blasés* ought to be thankful, and Mr. Haden has had an advertisement among the wealthy and the titled, which ought also to be a cause of thankfulness—at least to him.

WE have received the *New Orleans Picayune*, detailing a meeting of the New Orleans Medical Protective Association. At this meeting all the members agreed that they would not make contracts of service with any associations. It appears that there are in the city a number of what seem to be mutual benefit associations, and that it has been the custom for physicians to agree to serve them by the year at "five, ten, and twelve cents" a visit, as the case might be. At the meeting it was announced that all the holders of such positions had tendered their resignations. If the profession keep together, no doubt the practice of contracting with associations will be done away with. Probably this is the best solution of the question; but we have often wondered whether it would be possible to regulate, by a stern professional law, the "contract system" without abandoning it. It certainly would be better for an impecunious doctor to attend at fifty cents a visit by contract than at \$0.00 without contract.

THE Royal English Commission appointed to consider the subject of vivisection is composed of Lord Cardwell, Lord Winmarleigh, Mr. Forster, Sir John Karslake, Mr. Erichsen, Prof. Huxley, and Mr. Hutton. The London *Lancet* says of them, "Those who, like ourselves, desire to see the subject calmly and dispassionately considered from all points of view will regard these names as a guarantee that such will be done."

Mr. Hutton has taken an active part against vivisection, but is said to be a well-meaning, candid man, and Prof. Huxley is certainly no less committed in favor of vivisection.

REMARKABLE SUCCESSION OF BREECH-PRESENTATIONS.—Dr. Nourse (*Clinic*) relates the case of a lady aged forty-three—married twenty-five years—had eleven children, all being breech-presentations. Mother was a healthy woman, medium height, with a well-developed pelvis. Children were also well developed, of fair size, and with heads of the usual size. The only peculiarity of the labors was the regular recurrence of the exceptional presentation.—*Detroit Review of Medicine and Pharmacy*.

CORRESPONDENCE.

BALTIMORE, July, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The medical societies have adjourned until September; the colleges are making additions to their hospitals, and otherwise preparing for the fall campaign; Prof. Gilman has gone to Europe, and expects to bring back some famous men to fill chairs in the Hopkins University; the Hopkins Hospital still shows no signs of life; and the whole city, sweltering in the midsummer heat, enjoys the hydro-sulphuretted odors of the basin and the balmy breezes from the Falls.

The infant mortality here has been excessive. One week, out of 269 deaths, 168 were under five years, and about 90 of these were returned as from cholera infantum.

I was quite interested in an article in a late number of the *Times*, from Dr. Comegys, on summer-complaint. Cholera infantum is considered by many of our physicians as a heat-fever. The nervous system of the child, being very delicate, feels the full force of the extreme heat, and the vomiting and purging are only evidences of disordered nervous action, and not indicating inflammation of the stomach and bowels. Two forms of the disease are recognized,—the congestive and the syncopal. The former is the most dangerous, and requires the copious use of cold water externally and quinine internally. The syncopal requires quinine and stimulants, given in small and frequent doses. After the urgent symptoms have passed, bismuth may be used should the diarrhoea persist, but I have seen many cases, apparently dangerous, promptly relieved by quiniæ tannas, gr. $\frac{1}{2}$ -j; elix. valerian. ammon. (not Hubbell's), gtt. v-xx, every two hours. I think the success with this mode of treatment is greater than with the old calomel, chalk, and astringents. Of course, the large majority of our physicians adhere to the entero-colitis pathology, and treat accordingly.

I was pleased to see a paragraph that old Jeff. had purchased ground adjoining the college building for the purpose of erecting a hospital thereon. As I am an alumnus of that school, I earnestly desire its prosperity.

Here we have three schools.

The University of Maryland has a small but well-managed hospital under its control, to which it has just added a new wing, about 30 by 90 feet, and three stories high. The professors are Drs. N. R. Smith, Chisolm, Johnston, Donaldson, Chew, McSherry, W. T. Howard, Tiffany, Miltenberger, Miles, and Aiken.

The Washington University has also been making some additions to its hospital. This building, situated near the centre of the city, gets nearly all the accident cases, and thus its wards are generally well filled. Drs. J. F. Monmonier, Arnold, Lindsay, Trist, Scott, Clagett, Green, and J. N. Monmonier are professors.

The College of Physicians and Surgeons has established a lying-in hospital, which is in a flourishing condition, and fills a want long felt in this city. The pro-

fessors are Drs. Lynch, Erich, Brown, Latimer, E. L. Howard; Atkinson, Friedenwald, Bevan, Opie, and Goolrick. The other hospitals of the city are, Hebrew, St. Agnes's, St. Joseph's, Church Home, Union Protestant Infirmary, Bayview Asylum, and Mount Hope.

We have ten dispensaries, which do much good and much harm. It is impossible to prevent persons able to pay for medical services from receiving aid from our charitable institutions; and, like all other cities, we are educating a class of permanent paupers.

Some time since, I wrote that our city enjoyed the blessings of the night-cart. I am happy to say that the above statement is no longer true. The firmness of the mayor and our efficient commissioner of health, Dr. James Stewart, has given us what we never had before,—a summer free from the noise and stink of the sink-cleaning brigade. The odorless apparatus has free control, and gives general satisfaction to the citizens. Our city council showed its appreciation of the voting capability of the night-force by repealing the ordinance which gave us relief; but the mayor vetoed it. Our council deserves no credit for enacting this ordinance, as it was done under compulsion. Baltimore County was tired of the nuisance, and gave the city notice that unless it was stopped injunctions would be applied for. So, for a few months at least, we are free.

Yours, etc.,

MEDICUS.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MAY 27, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Kidney from a case of hæmaturia in an infant.

DR. JOS. G. RICHARDSON presented the specimen, showing a curious natural injection of both the convoluted and straight portions of the uriniferous tubules with blood-casts, and remarked that the organ had been sent to him by Dr. M. B. Wright, of Cincinnati, Ohio, for microscopical examination; the case being one in which supposed pigment-flakes were found in the urine, and, he believed, also in the blood.

Dr. Wright was preparing a paper in relation to a series of these cases which had occurred in his hospital wards, for the forthcoming volume of the Transactions of the American Medical Association, but had kindly permitted the exhibition of this specimen, and furnished the following brief history of this and similar examples of the disease:

"In three or four days, or longer, after birth, a dingy appearance of the (child's) surface is observed. A curdy exudation is scattered over the mouth, the urine becomes dark, and soon a black sediment, in more or less quantity, is observed on the napkins. Some of the little patients have died within twenty-four hours, others have lived several days, and a few have recovered. The urine has been carefully examined chemically, with negative results merely."

Dr. RICHARDSON exhibited under the microscope a thin section cut in the axis of one of the pyramids of

the kidney, and stated that by tinting the contents of tubules, in similar preparations, with aniline or iodine (according to his method for the diagnosis of blood-stains), he had been able to demonstrate, and even accurately measure, the red blood-corpuscles of which they were composed.

Biliary calculi impacted in the left branch of the hepatic duct, attended with numerous cystic formations in the corresponding lobe of the liver.

Dr. R. M. BERTOLET presented the specimen, and furnished the following history :

"The specimens were obtained at the obduction of J. G., æt. 65, who was admitted into the Philadelphia Hospital in a semi-comatose condition upon May 20, 1875. No previous history of the case was obtainable; death ensuing in less than twenty-four hours. The clinical records are also very unsatisfactory. There was noted a moderate jaundice; high temperature; hurried respiration; hypostatic dulness, and vomiting.

"*Autopsy.*—The lungs were cedematous; bronchi filled with a frothy serum; heart slightly enlarged; the left ventricle hypertrophied; semilunar valves thickened; aorta atheromatous. The stomach presented several small patches of erosion and ulceration of the mucosa. Towards the pylorus the serous membrane was intensely injected, and had formed slight adhesions to the hepatic organ. The mesentery and the serosa covering the small intestines were likewise, at points, strongly injected, with here and there ecchymotic blotches. A very small quantity of flocculent serum was found in the abdominal cavity. There were no intestinal ulcerations. The spleen was flaccid, reduced to a soft, almost pulpy, mass, somewhat reduced in size. Kidneys were enlarged, soft, with cortical cloudy swelling of the convoluted tubules; the capsule separating very readily.

"The liver was of normal size, very much softened, with a slightly roughened capsule. In the left lobe a number of cysts were seen bulging above the level of the convex surface. Upon removing the viscus, one of these thin-walled cysts was ruptured, and a quantity of yellowish, creamy matter escaped into the abdominal cavity. Probably a similar escape of pus took place during life, thus giving rise to the slight peritoneal inflammation. Examining the liver more minutely, it is seen that the left lobe throughout presents numerous cystic patches, which communicate with one another. These cysts vary in size from a small pea to that of an almond. They are filled with thick, yellowish, turbid fluid, often mingled with numerous small, black and ochre-colored concretions. In the transverse fissure of the liver two cylindrical-shaped biliary calculi, each about the size of a marble, were felt completely occluding the left branch of the hepatic duct. When first removed, the outer layers of these concretions appeared soft and crumbly; the interior nucleus being much firmer in consistence and darker in color. There was decided thickening of the walls of the left branch of the hepatic duct; while at the same time the surrounding connective tissue was hypertrophied to such a degree as firmly to bind down these two calculi in their position in the hepatic duct. The index-finger could be readily inserted into this portion of the biliary tube after removal of the calculi. Immediately beyond the point of constriction ampullar-like dilatations began to be developed, attaining their maximum size, however, in the ultimate twigs of the biliary ducts towards the periphery of the organ, where the least resistance presented itself; there forming the numerous cystic distensions seen strewn over the entire left lobe.

"The gall-bladder was filled with a thin, yellowish secretion, free from concretions. The ductus communis choledochus, as well as the cystic and hepatic

duct, excepting its left branch, were found to be freely pervious.

"That these cysts, so closely resembling in appearance multiple hepatic abscess, are the resultant of the obstructions in the hepatic duct, is evident from the fact that they contain a greater or less number of small biliary concretions, and that their walls at points still present the remnants of a columnar epithelial lining. Further proof of such an origin is afforded, should any be required, in the microscopical appearances presented by the hepatic parenchyma even at a considerable distance from the cysts.

"The ultimate radicles of the bile-ducts are microscopically seen to be filled, at a few points actually dilated, with a fine granular biliary coloring matter. Often entire meshes are formed by these blackish lines of pigment in the biliary capillaries, each enclosing a single liver-cell; so that we have before us the finest picture of a natural injection of the gall-capillaries, excelling by far the famous Chronszczewsky artificial preparations. This pigment-matter marks not only the periphery of each lobule, but extends into the very centre of the acini; and here and there are also found single large fragments of gall-pigment lying between the hepatic cells. The latter are undergoing atrophic changes and disappear under the encroachments of the cysts. The hepatic cells in this specimen are unquestionably undergoing fatty degeneration, nor do I believe that this condition is entirely attributable to post-mortem changes, as Heinrich Mayer* claims. This experimenter succeeded in filling the biliary radicles with granular pigment, by ligating the ductus choledochus of various animals, but states that gall-stasis is not attended with fatty degeneration.

"Leyden,† on the other hand, concludes from his experiments that fatty infiltration of the hepatic cells does occur, which eventually leads to the atrophy changes.

"Wyss also noted the same phenomena where the hepatic duct had become closed by a carcinomatous nodule. It will be seen without further citation that there is a certain amount of conflicting evidence as to the processes which cause the dissolution of the secreting parenchyma, and I desire to place this case on record as one attended with decided fatty infiltration. It is generally admitted that the disappearance of the hepatic cells is not due to any solvent action of the retained biliary secretion itself.

"Without going into minute details, I can fully confirm the statement of Mayer, that the protracted stasis of gall causes an increase of the connective tissue of the liver, not only around the blood- and biliary vessels, but also in the centre of the lobule, where the sustentacular substance is increased to such an extent as to push the secreting cells asunder.

"The presence of calculi in the hepatic duct is an extremely rare occurrence. But a comparatively limited number are recorded, and of these many were kept back by the simultaneous filling of the common duct with calculi. Although in this specimen we find the concretions firmly clasped in position, yet upon their removal the biliary duct is not stenosed, and it is a difficult matter to explain, in the absence of new growths or other obstructions, how they came to be retained in this site, where the tube is decidedly much wider than any of its branches. No account seems to have been hitherto taken of the part that is probably played by the numerous blind ramifications in the transverse fissure of the bile-duct, now generally designated by histologists as *vasa aberrantia*.

"These receptacles for bile, which are quite numer-

* Wiener Med. Jahrb., 1872.

† Beiträge zur Pathologie des Icterus, 1866.

ous around the hepatic duct, may, in a yet undetermined manner, account for the arrestation of calculi in this site. Biliary cysts due to mechanical obstruction and stenosis of other portions of the gall-duct have been frequently recorded, and they seem to be often met with in sheep afflicted with distoma hepaticum. Rupture and escape of the cystic contents into the peritoneal cavity occasionally happen. The clinical picture presented by these cases is not yet as sharply delineated as desirable, and I regret that this well-marked case does not enable us to learn anything in this respect."

Medullary carcinoma of the left ovary.

Dr. J. EWING MEARS presented the specimen for Dr. W. W. KEEN, who furnished the following history:

"Mrs. A. S., æt. 46, of West Chester, was sent to me May 1, 1875, by Dr. McClurg. She began to menstruate at 15, and ceased at 44; was always regular, and did not usually suffer much pain. Married at 19, and her only child was born one year later. Has never had any uterine trouble. Her general health has been good until within two years. She first observed a swelling just above the right groin, about two years and a half ago, but it was not painful. In September last, after lifting a heavy basket, she observed that it had changed its place to the middle line. She had at that time considerable abdominal pain, and was sick some three or four weeks, but was not in bed. In October last, Dr. McClurg tapped her and removed five gallons of a greenish, viscid fluid, the operation being followed by considerable peritonitis. Her health was better after she was tapped, but the abdominal swelling again increased considerably. Of late she had not suffered much pain, but, from general discomfort, life was becoming a burden.

"May 1, 1875.—On examination, she is seen to be a thin, spare woman. Her abdomen measures, from the ensiform cartilage to the umbilicus, six inches; thence to the pubes, nine inches; between the iliac spines, sixteen inches; and the greatest abdominal girth, a little below the umbilicus, is thirty-three inches. The swelling is almost wholly below the umbilicus. A considerable amount of ascites is readily recognizable, beneath which the tumor is distinctly felt. The anterior parietal adhesions are limited to two irregular spots of about three inches square, the one surrounding the point of tapping, the other below it, and corresponding to a hard mass. The ascitic fluid flows around these adhesions, and reveals them easily. No adhesions existed laterally to the abdominal walls. The whole mass was, however, movable with difficulty either from side to side, or from below upwards. Palpation showed that the upper part of the tumor was distinctly cystic; the lower part, however, was solid. Anteriorly there extended from the pubes, obliquely to the right, a mass feeling somewhat like an elongated, irregular uterus; but the later examination of the uterus made it very doubtful that this was the uterus.

"The vaginal examination showed the os and cervix in about their normal position, size, and relations. The tumor could be felt behind the womb, but the cervix did not fade into the tumor, for a depression existed between them. The sound entered the uterine cavity upward, and somewhat to the right, two and a half inches.

"The uterus was scarcely movable at all independently, and movement of the tumor communicated motion to the uterus. The tumor could also be felt by the rectum, and its general pelvic examination left no doubt that the pedicle was very short and the adhesions probably pretty firm, but not very extensive.

"May 20.—By the aspirator I drew off a small quantity of the fluid for examination. I punctured the cyst through the adhesions, so as to avoid the peritoneal

cavity. The fluid was purulent-looking, and showed on examination some compound granular corpuscles and a few blood- and pus-cells; but the morphological element was mainly the distinct ovarian cell.

"May 22.—The tumor was removed at St. Mary's Hospital, in the presence and with the assistance of my colleagues, Drs. Grove, Schell, and Mears, and Drs. McClurg, Stewart, Porter, Griffith, with several others. After tapping the main cyst I found that the lower mass was too solid for any further diminution in size, and my incision had to be extended from the umbilicus six and a half inches downwards nearly to the pubes, to admit of its removal. The parietal adhesions were easily broken up; a few were found above and behind, to the intestine and omentum, and the mass was then turned out of the abdominal cavity. It was so large and solid that it hid everything below its mass, and I was obliged to tie its large base with a stout ligature, and then remove the greater part of the tumor at once, by cutting through its substance. Having done so, the base of the tumor (for it could not be called a pedicle) was found to be attached directly to the uterus, the rectum, and the left side of the pelvis. The parts of the tumor which had been left were now removed. Three large stout ligatures were passed around the broad attachments, two at the uterine and one at the pelvic attachments. These secured some large vessels. Considerable trouble was caused by these vessels and numerous smaller ones, so that eight ordinary ligatures were required. These were cut off short, but the three large ones were brought out of the abdominal wound. The attachments were touched with Monsel's solution, and the wound was closed by eight silver-wire sutures. The operation lasted two hours.

"The tumor consisted in its upper portion of one large cyst, containing about four pints of fluid like that before described, besides two or three quite small cysts. The inner surface of the large cyst was coated with soft, almost grumous papillary growths, numerous detached masses of which made up a sediment in the fluid. The lower part was quite a hard solid mass, divided by distinct septa of connective tissue into smaller masses, which could be peeled out of their loculi. These smaller masses were whitish in color, and again subdivided into still smaller similar masses.

"She was placed in bed with some hot-water bottles, though she was not very cold, and one-fourth grain of morphia was given hypodermically. In a short time she became conscious, and reacted well, though vomiting occurred occasionally. Nothing was given for three hours, but then beef-tea and milk-punch in small quantities were given every hour. Her pulse in the evening was 124, and temperature 101.2°. Another one-fourth grain of morphia was given to produce sleep. She suffered no pain.

"May 23.—In the morning her pulse was 126; temperature 100.8°. She had not slept any, had rejected the beef-tea utterly, but retained the punch. There was no pain, but the belly was a little tender. She passed a small quantity of water. Her general condition was much depressed. I continued the punch and ordered broken ice and a cup of iced tea.

"In the evening her pulse was 144, and very weak; her temperature 101.8°; her belly tender. A little oozing of bloody serum had taken place during the day. She was bathed in perspiration, was restless and despondent. From this time she gradually sank more and more, and died at 8 A.M. the next morning, May 24.

"Autopsy, May 24, at noon. The wound was well united throughout, except where the ligatures emerged. At each ligature there was a little pus. The intestines were all glued together with lymph of recent formation below the level of the umbilicus. At this level the omentum was attached to the belly-wall transversely,

and divided the main peritoneal cavity into two parts. In the upper the evidences of old inflammation and its resulting adhesions were seen; in the lower the recent inflammatory changes, the results of the presence of the tumor and the operation. No hemorrhage had occurred after operation.

"The uterus and right ovary were removed, with a portion of the rectum. The tumor was found to have been attached to nearly the whole of the left half of the uterus laterally and posteriorly, and to the rectum in Douglas's cul-de-sac. From this rectal attachment and deep on the posterior surface of the uterus the troublesome hemorrhage had taken place, and also from the pelvic attachment of the left broad ligament, which was the pelvic attachment. The right ovary was somewhat enlarged, and had contracted some adhesion to the pelvis.

"All the specimens are deposited in the Museum of the College of Physicians.

"Dr. J. G. Richardson kindly examined the specimens for me, and reports as follows:

"Scraping the surface of a fresh incision into the ovarian tumor you left with me yielded an abundant milky juice, containing multitudes of rounded, oval, caudate, and multiangular cells, with large nuclei. Thin sections from the growth exhibited similar cells heaped together in the alveoli of a loose but rather abundant struma, the individual cell-elements being without intercellular substance. The tumor seems, therefore, to be a rather hard variety of encephaloid or medullary carcinoma.

"The right ovary contained a dark-brown fluid, in which compound granular corpuscles, plates of cholesterol, and "Drysdale's ovarian cells" were abundant. Its internal wall, on incision, displayed a peculiar plicated arrangement, strikingly analogous to that of the *corpus luteum* of pregnancy."

Dr. MEARS said he had examined the fluid and did not find in it the so-called ovarian cell in such numbers as Dr. Keen. He thought he had at times been able to diagnosticate cancer of the ovary by examination of fluid drawn from the abdomen. In this case, however, he was unable to do so, but had concluded that this was a multilocular cyst, in which suppuration had occurred. The discovery by Dr. Keen of the so-called ovarian cell in such large quantities in the fluid derived from this case by tapping, would seem to deprive this cell of its pathognomonic character, since the specimen is pronounced by Dr. Richardson to be a true medullary cancer.

Dr. BERTOLET said that he would refrain from saying anything about the so-called "ovarian cell," as being a matter still held *sub judice* by a special committee of this Society, but he thought that, as a scientific body, it was wellnigh time that we should drop allusions to and discussions about "cancer-cells," of which such frequent mention had been made. Cancerous tumors could not be diagnosticated by simply examining the juices or rough scrapings, but could only be recognized by careful section and examination of the cells in relation to the stroma. The mere presence of a greatly and variously altered epithelium did not suffice to distinguish a carcinomatous growth from a benign adenoma; and many other species of tumors, like a simple retention-cyst, may present us with as many varied forms of cell-growth. The alveolated connective-tissue stroma is as important a factor as the "epithelial" element; either one, without the other, can never constitute a carcinoma. "Cancer-cells" are things of the past, and by us, also, should be irretrievably consigned to oblivion.

Dr. MEARS said he would like to ask Dr. Bertolet whether or not it was possible to diagnosticate cancer by examination of products obtainable during life.

Dr. BERTOLET replied that it was formerly alleged that cancer of the kidney could be determined by the presence in the urinary sediment of cells derived from the debris of the breaking-down growth. These various forms of cells—atypical epithelium—have now been abandoned as worthless for the diagnosis of renal cancer. Occasionally, it is true, fragments are discharged so large as to permit the recognition of an *alveolar structure*, when teased or cut in thin sections; but very often even such fragments are so far advanced in the necrobiotic process as to preclude such a recognition.

Dr. MEARS said he could recall at least one instance in which he had examined the fluid drawn from the abdomen and concluded that the case was one of cancer of the ovary. He was present at the operation, and presented the tumor to this Society. The specimen was referred to the Committee on Morbid Growths, and reported by them to be one of cancer. He was not as yet a believer in the existence of pathognomonic ovarian cell, and in the discussions in this Society he had expressed his disbelief in the existence of a distinctive cancer-cell. He fully recognized that the only proper method to determine the character of growths was to examine them in section, in order to study the relation of the cells to the stroma, but he felt sure that he had at times observed differences in the fluids in cases of ovarian disease which caused him to declare that the growth was not an ordinary cyst of the ovary, but a cancer.

Dr. JOHN ASHHURST, Jr., said that he thought that in our zeal for modern methods of investigation (the excellence of which no one could be more ready to admit than himself) we should not overlook the circumstance that cancer had, as a matter of fact, been frequently recognized in past years by the examination of scrapings, or of the so-called "cancer-juice," and that the investigations of Paget and other eminent pathologists had been almost entirely conducted in this way. While no one at the present day probably believed that there was any definite "cancer-cell," yet he thought the existence in any particular specimen of a great variety of cells of different sizes and characters, and of multifarious shapes, furnished probable, though not certain, evidence of the presence of cancer. It must be remembered, too, that even with the modern method of examining thin sections it was not always possible, without repeated examinations, to determine whether a given growth was of a carcinomatous or a sarcomatous nature, the same tumor, perhaps, presenting in most parts cells in constant relation with an intercellular substance (sarcoma), and yet, in certain places, nests of cells without any intercellular substance, when the growth would have to be called a *carcinomatous sarcoma*. Hence, while fully agreeing with Dr. Bertolet as to the superiority of the modern mode of studying the minute anatomy of tumors, he thought that, nevertheless, some information of practical value might be gained by examining scrapings or expressed fluid, and that it was not at all unreasonable, therefore, to suppose that a microscopic examination of the liquid removed by tapping might afford ground for a probable, though doubtless not a positive, diagnosis of cancer.

Dr. JOSEPH G. RICHARDSON said that he had now in his possession specimens of the discharge from a case of tumor under the jaw showing characteristic pearly globules by which he was enabled to make a diagnosis of epithelioma, without any examination of sections from the growth.

Dr. JAMES TYSON said he had recently more than once stated that in our modern methods of study of morbid growths he feared that the cell itself was being too much overlooked. Certainly no one would accuse him of claiming the existence of a specific cancer-cell; but at the same time, having had some experience in the older

methods of scraping and dissecting, as well as the more modern of hardening, staining, and section, he felt that there were certain peculiarities of the cells of cancerous growths considered *in toto*, the presence of which alone justified more or less suspicion of malignancy, in a clinical aspect, at least. These characters had been well described by his friend Dr. Ashhurst, and need not therefore be repeated. To those named might also be added the large numbers of nuclei, and the large size of the nuclei in relation to that of the cells themselves. Dr. T. did not wish, however, to be considered as advocating a study of the cells only, in making the diagnosis of cancer, but thought that both methods should be combined.

With regard to cancer of the kidney, he had to say that in a very large number of examinations of urinary sediment from cases of suspected cancer, and in some of which cancer was found to exist after death, he had never met any cellular or other elements whence the presence of this disease could be suspected. At the same time, he thought it not impossible that, in the disintegration of the organ, portions might descend to the bladder, which would aid or confirm a diagnosis, and he saw no reason to doubt the accuracy of observation by such observers as Beale, Hoffmann and Ultzmann, and others bearing on this point.

Dr. RICHARDSON thought it might at least be said that while the cellular elements in normal tissues grow according to a law of uniformity, those lying closely apposed resembling each other so long as constituting the same tissue, the cells of cancer grow in a *lawless* and irregular manner, resembling those of various other tissues as well as those in which they happen to be seated.*

Dr. BERTOLET thought that if Dr. Ashhurst were to have plunged his trocar into the cavity of the tumor of the breast which had been this evening reported by the Committee on Morbid Growths as a cysto-sarcoma, he would have drawn out many epithelial elements, while the chief mass is in reality a sarcoma. In fact, the contents of the large cyst had been examined microscopically, but were found to be mostly epithelium, and so destitute of any characteristic features that no allusion to their appearance was deemed called for.

The PRESIDENT referred to the interesting question of the microscopic appearances in the urinary sediment in cases of cancer of the kidney. He had had the opportunity of carefully examining the urine in quite a number of such cases, and had found the results most uncertain. The great variety of form and size of the cell-elements derived from the epithelial lining of the urinary passages (perhaps especially from the bas-fond of the bladder) simulate at times the cell-forms of carcinoma, and on several occasions when the autopsy showed merely pyelitis, suspicion of cancer of the kidney had been aroused in this manner. On the other hand, in cases of undoubted renal carcinoma the microscopic study of the urinary sediment gave entirely negative results.

It would seem as though much of this discussion turned upon the precise classification adopted for tumors and neoplasms. It is of course well known that this has varied much at different times, and notably since the earlier writings of Paget. There can be no doubt that the latter observer and others of his school

very frequently made a correct diagnosis of cancerous growths, so called under their classification, because the character of the expressed juice and particularly the cell-forms it contained formed an important feature in the characteristics of a cancer. But at the present time there exists an almost unanimous disposition to accept the classification of recent writers, in which cancer occupies a perfectly definite place, not in the least dependent on the character of juice that can be expressed from a cut surface, nor on the cell-forms present, but upon certain definite anatomical relations and arrangement of cells and intercellular stroma. According to this latter view it is, of course, necessary to employ the mode of examination which will alone afford a demonstration of these relations; and it is evidently impossible that a diagnosis can be made from the examination of fluid. It would seem that, with this conception of the question, the assertions made by Dr. Bertolet were well founded.

Vesical calculus of small size, producing marked symptoms.

Dr. JOHN ASHHURST, Jr., exhibited a vesical calculus, weighing less than two grains, removed by lateral lithotomy, from a boy, one week previously. The symptoms of stone in the bladder had existed only about three weeks, but had been unusually severe, several attacks of complete retention of urine having occurred, and the violent straining during one of these attacks having caused rupture of a blood-vessel in each orbit. The stone appeared to be of the uric acid variety, and there had been evidences of renal calculus before the development of vesical symptoms. Entire relief had been afforded by the operation.

GLEANINGS FROM OUR EXCHANGES.

SALIVARY CALCULUS IN THE PAROTID DUCT (*Edinburgh Medical Journal*, March, 1875).—Mr. Joseph Bell reports the case of a young lady, æt. 23, who for five months noticed a hard swelling in the left cheek, far back, nearly opposite the last molar tooth. There was not much pain except at times, when the tumor increased in size. There was much thickening of mucous membrane, and a constant discharge of pus into the mouth. There was also considerable fetor. The mucous membrane was red, swollen, and at one point a most malignant-looking fungous mass of granulations protruded. A gum-boil was supposed to have originated the mischief. Finding that all the pus came from one point, Mr. Bell passed in a fine grooved probe and succeeded in striking a hard mass at about the distance of an inch from the opening. Next day she was put under chloroform, and by slitting up Steno's duct to the distance of nearly an inch, it was found possible to dislodge and remove a pear-shaped salivary calculus, about the size of a hazel-nut. A very rapid recovery from all the symptoms ensued, and no deformity whatever remained.

TREATMENT OF ABSCESS OF BREAST BY COMPRESSED SPONGE (*New York Medical Journal*, June, 1875).—A patient had been suffering from mammary abscess for three weeks, but without any special benefit from treatment in checking the discharge of pus. It was decided to try the effect of compressed sponge, and for this purpose a sponge about ten inches in diameter was subjected to pressure and then applied by means of a bandage over the breast. After it had been in use forty-eight hours the abscess was completely cured. No pain was experienced by the patient, and in this case the opening in the breast was three inches above the de-

* [I have sometimes illustrated to my students the nature of this *lawless growth*, which I conceive to be so important a characteristic of the cells of cancer (as distinguished from Lebert's cancer-cell), by comparing it to that manifested in the development of the fungus producing the "smut" of our Indian corn. The relation held by the huge, distorted, ugly, and *lawlessly growing* diseased grains to healthy grains evenly ranged in a ripe ear of corn, is strikingly analogous to that subsisting between the large, deformed, and *lawlessly growing* cells of carcinoma, and the equal, symmetrical, and regularly arranged cellular elements of normal tissue, as, for example, the mammary gland, which the malignant tumor may invade.—J. G. R.]

pendent part of the abscess. In applying a sponge to the breast in this class of cases, it is found of advantage to compress it when dry. After it is applied to the breast and firmly secured in position, a little water is poured upon it to cause expansion and the necessary pressure.

CASE OF GONORRHEAL OPHTHALMIA WITH PECULIAR FEATURES (*New Orleans Medical and Surgical Journal*, May, 1875).—Dr. V. Grima reports a case of gonorrhœal ophthalmia, which, after the duration of a week, suddenly got well, together with the gonorrhœa. At the same time both of his knees, his elbow-joints, and his wrists grew swollen and painful. This lasted about ten or twelve days, and then got well rather rapidly, when his eyes again became painful, and, on examination, he was found to have rheumatic iritis. He finally recovered entirely.

OVULATION WITHOUT MENSTRUATION (*Chicago Medical Journal*, June, 1875).—A lady, married at 25, became pregnant, and was delivered in about ten months. The child was nursed twelve months. After this the mother menstruated six times. Her second child was nursed five months, until the baby died. Since then a third and a fourth child have been born, and a fifth pregnancy is now going on, each child having been nursed twelve months, yet during the past six years she has not menstruated once.

SALICYLIC ACID IN CHRONIC CYSTITIS (*New York Medical Journal*, June, 1875).—In chronic cystitis the bladder has been washed out with a solution of salicylic acid, containing one part in five hundred of water. The method has been to make four injections of one ounce each, every morning and evening. The acid not only removed the disagreeable odor of the urine, but, in a short space of time, freed it from pus. In empyema, a solution of the same strength has been employed with very valuable results.

ARE THERE ANY MEANS BY WHICH THE SEXES CAN BE PRODUCED AT WILL? (*New Orleans Medical and Surgical Journal*, May, 1875).—A series of observations were made by M. Thury, a French veterinary surgeon, with a view to discover, if possible, whether, and in what manner, the sexes could be produced at will in animals. The result arrived at was: that when the male had connection with the female in the beginning of heat in the female, the offspring were females; and when had towards the termination of heat, the result was a male. These results were published; and others who were engaged in raising animals pursued the same course of observations, and verified, by the results obtained, the truthfulness of the theory advanced by M. Thury from his observations. From observations made by medical men with regard to the development of sexes in the human subject, the result arrived at was that in a conception taking place at an early period after the menstrual flow had ceased, the product will be a female; and the farther removed from that period (always omitting four or five days anterior to the following monthly illness), the more likely is it that the child will be a male. We generally find that where there is a difference of fifteen years, more or less, between the ages of parents, with the father the elder of the two, the children are usually males; and this is accounted for on the ground that the father has not the same amount of desire as a younger man; some time usually elapses after the flow before copulation takes place.

CONVERSION OF BRUCIA INTO STRYCHNIA.—Two alkaloids—strychnine and brucine—occur in the various strychnos species. These, on superficial view apparently very dissimilar bodies, are, however, aside from their occurrence in the same species of plants, chem-

ically very closely connected. By an inspection of their respective formulæ, it appears that by the assimilation of four atoms of oxygen and the separation of two molecules each of water and carbonic anhydride, brucine can be transformed into strychnine. This is effected by gently treating brucine with four or five times its weight of diluted nitric acid. After the effervescence of carbonic anhydride has ceased, the deep-red solution is concentrated, treated with potassium hydrate in excess, and shaken with ether. The ethereal solution, on spontaneous evaporation, yields a red-colored mass containing a red pigment, a yellow resin, and a base. By recrystallization, the latter was obtained in a pure state, and found, by its excessively bitter taste and all of the other characteristic reactions, to be strychnine. The transformation of brucine into strychnine is not only a remarkable fact in itself, but is also highly important in a toxicological view, as it again points out the great caution that must be exercised in such investigations where oxidizing agents are employed.—*T. L. Sonnenschein*, in *Pharm. Zeitung*; *Pharmaceutical Gazette*, July, 1875.

MISCELLANY.

THE FORM OF LIGHTNING-RODS.—Knowing that electricity at rest always tends to diffuse itself on the surface, in fact, that it always *confines* itself to the surface, it became at an early period a question whether electricity in motion did not follow the same law. Pouillet determined the question in a very ingenious manner. He took a cylindrical wire of a certain size, and measured the resistance which it offered to a current of electricity. He then rolled the wire out flat and measured the resistance again; it was found to be the same, although it is evident that the extent of the surface of the conductor was by this means greatly increased. Other experimenters have determined the question by different methods, but always with the same result. The committee of the French Academy, which included Becquerel, De la Rive, Pouillet, and others, adopted a solid square bar as the best form for lightning-rods; and Sir William Snow Harris, though often quoted as favoring rods which present a large surface, says, "Provided the *quantity* of metal be present, the form under which we place it is evidently of no consequence to its conducting powers, since it would be absurd to suppose that a mass of metal, under any form, did not conduct electricity in all its particles; indeed, we know that it does so."—*Prof. John Phin*, in *Popular Science Monthly* for August.

DR. EUGENE PENDLETON describes in the *Medical News* the case of the most unkillable man on record. He fell sheer 258 feet by actual measurement, and suffered only such trifling injuries as concussion of the brain, broken ribs, fracture of the radius, and dislocation of the humerus, downwards and backwards. About twenty-four hours afterwards, all symptoms of concussion passed off, but a severe attack of pneumonia followed, from which he made a good recovery, and is now as well as ever.

MEDICAL LEGISLATION.—The *Medical News*, in reply to the desire of the *New York Medical Record* to know "what our medical brethren of Pennsylvania have gained by this law," says,—

"When our cotemporary will inform us what protection lambs ever received from wolves, we will be enabled to gratify his desire for information.

"Lambs, guided by *instinct*, fly from the wolves, but medical men are supposed to be influenced by a higher faculty,—*reason*. This prompts some of the well-meaning but inexperienced among them to seek assistance from our political legislatures, and they obtain such protection as the poor frogs in the fable obtained when they prayed to Jupiter for a king to govern them: they got King Stork."

OF M. DÉMARQUAY, the noted Parisian surgeon, who recently died of cancer of the stomach, the Paris correspondent of the *British Medical Journal* says,—

"The name of Démarquay is familiar to the medical world, as he not only distinguished himself by his writings, which proved him to be a *savant* in the true sense of the word, but was also one of the ablest and most practical surgeons of the day. M. Démarquay was surgeon to the 'Maison Municipale de Santé,' more familiarly known as the Maison Dubois, where he had made himself very popular. He was far above political influences, which is a rare thing for a man of his position in France, so that he had none but friends in the ranks of all parties. This he showed during the siege of Paris, and subsequently during the Commune, when, as surgeon and one of the founders of the 'Ambulance de la Presse,' he rendered the most unreserved and signal service. M. Démarquay was a member of the Academy of Medicine, and, had he lived, would doubtless have one day taken his seat at the Institute. His professional services were rewarded by the State by promotion to the dignity of Commandant of the Legion of Honor. Born of poor parents, M. Démarquay died a millionaire. He was never married, and, consequently, bequeathed a portion of his large fortune to his poorer relations, and the remainder was distributed as follows: £4000 to the Paris School of Medicine for the foundation of an annual prize; £400 was reserved and made over to one of his friends and disciples for the purpose of putting together and publishing his loose manuscripts."

NEW PROPERTY OF GLYCERIN.—R. Godeffroy, on examining a chemically pure glycerin, found that when heated to 302° Fahr. it took fire, and burned with a steady, blue, non-luminous flame, without diffusing any odor or leaving a residue. The glycerin had the specific gravity 1.2609. This property enables glycerin of lower specific gravity to be burned by means of a lamp-wick. —*Medical Press and Circular*.

A REMARKABLE CENTENARIAN IN IRELAND.—The registrar of the Emly district, Tipperary, reports the following case: "The death of a centenarian," he says, "has been registered in my district during the quarter. She was a woman known in Emly by her maiden name,

Nance Lee; she has been registered as 108 years of age, but I have reason to know, from a family tradition concerning her, that her age was 111 years. During her youth she was gifted with wonderful bodily strength and activity, and as a girl used to follow across country a pack of black-and-tan beagles kept by a neighboring gentleman. For forty years of her life she acted as a carrier of bread between Tipperary and Emly. She used to carry all her goods in a bag on her back, and thus heavily laden she used to traverse daily sixteen miles. Up to the last she was strong and in perfect use of her senses, and she walked to and from the parish chapel the Sunday before she died."—*Medical Press and Circular*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 20, 1875, TO JULY 26, 1875, INCLUSIVE.

JANeway, J. H., ASSISTANT-SURGEON.—Granted leave of absence for four months. S. O. 150, A. G. O., July 23, 1875.

AINSWORTH, F. C., ASSISTANT-SURGEON.—To report to the Commanding General, Department of the Columbia, for assignment to duty. S. O. 147, A. G. O., July 20, 1875.

BROWN, P. R., ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of Dakota, for assignment to duty. S. O. 147, c. s., A. G. O.

The following-named Assistant-Surgeons (recently appointed) will report as follows for assignment to duty:

TAYLOR, B. W., in person, to the Superintendent United States Military Academy, West Point, New York, for temporary duty.

WORTHINGTON, J. CH., by letter, to the Commanding General, Military Division of the Atlantic.

ORIGINAL COMMUNICATIONS.

ATHEROMA.

BY J. MILNER FOTHERGILL, M.D. EDIN.,

Member of the Royal College of Physicians of London; Junior Physician to the West London Hospital.

THOSE changes which go on in the coats of blood-vessels, and are denominated atheroma, or endarteritis deformans (Virchow), form a most important part of pathology, and are also of equal importance when considered clinically. Of recent years much light has been thrown upon this previously dark piece of pathology, and from very hazy and erroneous views in the past we now possess a pretty distinct knowledge of the nature and causation of atheroma. For the initiation of our present knowledge we are indebted to Virchow. By his observations as to the method of growth of parenchymatous inflammations and of the slow growth of pathological connective tissue in various organs, the portal was opened and a path revealed which led directly to the correct interpretation of chronic changes in the walls of blood-vessels.

The morbid change known as atheroma consists of a growth of connective tissue beneath the tunica intima. At first there is but a slight thickening of the arterial coat, and the lining of the vessel is smooth and unaffected. In time, however, the tunica intima is involved, and the surface is very level or puckered. This morbid change may either be localized or general, according to circumstances. In the one case aneurism is the common consequence of the disease; and one part of the arterial system being diseased, the blood-pressure within the elastic bag—for that is what the arterial system actually is—distends or ruptures the affected part, and then there is a bulging of the external coat of the vessel. It does not follow that there shall have been any actual ulceration in the atheromatous patch: some unusual distention, either from a general rise in blood-pressure, or more often some effort impeding the flow in the diseased vessel, or some blow, rupturing the weakened walls, may occasion an aneurism. It is a disputed point whether or not an aneurism can arise in perfectly healthy blood-vessels. In the great bulk of cases, however, there is no doubt that the structural integrity of the arterial walls has been affected. It is at points of flexion, as the ham and the axilla, that this change is most frequent in an arterial system generally sound, or at points exposed to strain, as the outside of the aortic arch.

These localized atheromatous changes are less interesting than is general atheroma, except so far as they point to strain as the great cause of this growth of connective tissue in arterial walls. The evidence they thus furnish as to the causation of atheroma is invaluable. The researches of various writers, English and foreign, have collected together such a bulk of testimony as to the association of

atheroma with strain, that the subject of atheromatous change is no longer a doubtful one. The most striking illustration of the cause of this change is furnished by the fact that the lesser or pulmonic circulation is never, or almost never, the seat of such change so long as the mitral valve is healthy and competent, and the circulation in the lungs unimpeded. When, however, this valve becomes diseased, the blood-pressure in the pulmonic circulation rises, and a parenchymatous inflammation is instituted, which is found alike in the pulmonary artery and in the lining membrane of the left auricle. A thickened condition is found in all the coats of the blood-vessels, from the little festoons of atheroma in the pulmonary valves to the lining of the muscular chamber behind the lesion.

Strain leads to growth, and that growth is usually excessive and ill regulated, and consequently distorting. It need not necessarily be so, however. In a most interesting case recently reported by Dr. A. Wynne Foote, of Dublin, where old-standing interstitial pneumonia had led to extensive changes in the right heart, there was no atheroma. The pulmonary artery was as large and thick in its walls as a normal aorta. The pulmonary valves were also changed, being hypertrophied, and possessing corpora arantii, but free from valvulitis. The right ventricle was hypertrophied and dilated.

In this case the hypertrophy of the ventricle was accompanied by growth in the valves and arterial walls,—a corresponding growth, indeed, but so exquisitely balanced that there was really abnormal tissue-growth which had not run into disease. This case is most instructive. It demonstrates that other parts of the vascular system than the muscular can grow and increase in strength by development of normal histological elements. Hypertrophy of the muscles is accompanied by other tissue-growth until all the parts are strengthened. Unfortunately, however, this development of connective tissue is not often so neatly apportioned to the increased demand in the part as in the case just quoted; and so we have valvulitis and endarteritis deformans. The growth becomes excessive, and is not sufficiently well regulated, and then it becomes disease. It is but normal nutrition run riot, rather than a morbid process *per se*.

What course, however, that growth of connective tissue will take depends very much on its environment and the condition of the system in which it occurs.

Ere proceeding, however, to consider the circumstances under which atheromatous growth becomes itself degenerate, it will be well to consider its production and origin.

General atheroma is most commonly found in the subjects of chronic Bright's disease, especially where the morbid change affects the circulation chiefly. The effects of imperfect blood-depuration are felt very variously by different individuals. One will have articular gout; another will have gouty bronchitis; a third, eczema; a fourth, muscular rheumatism; a fifth, indigestion; a sixth, neuralgia,—all as the consequences of lithiasis, or blood charged with

excessive nitrogenized waste. According to the diathesis of the individual and the circumstances of the person, or of excessive use of any part, will be the outward manifestations of the one causal condition,—lithiasis.

In some families the circulatory system is ever involved; in others, again, different parts are affected, but the circulation remains uncomplicated. Why this variation should occur is yet unknown,—is perhaps unknowable. Very commonly the circulation is affected as one of the outcomes of kidney-disease.

Thanks to the observations and investigations of Traube,* George Johnson, Grainger Stewart, and others, the relations of these morbid changes are well understood, and form the most complete pathological process with which we are yet acquainted.

It can be briefly described thus: First comes imperfectly depurated blood; secondly, arteriole spasm; and thirdly, a rise in the blood-pressure. This last can be seen in a sphygmographic tracing long ere it can be recognized otherwise. The consequence of the persisting arteriole spasm is hypertrophy of the muscular coat of the arterioles, by which the high blood-pressure is maintained. This rise in the blood-pressure obstructs the blood-flow from the ventricle in its systole, and hypertrophy of the left ventricle follows (in some cases, chiefly in women, the hypertrophy is blended with dilatation). Betwixt the two hypertrophied muscular ends of the arterial system the pressure within the elastic arteries is heightened very markedly, and then the over-distention (*überspannung*) leads to the growth of connective tissue in the elastic arteries. That growth of connective tissue is atheroma.

Along with such atheroma we commonly find aortic valvulitis. The heightened blood-pressure and distention of the elastic arteries produces a stronger arterial recoil; and the aortic valves are closed violently, and consequently valvulitis ensues. The loud and accentuated aortic second sound so produced is insisted upon by German writers as one of the most important indications of chronic renal disease (Rosenstein, *Nierenkrankheiten*, zweiter Auflage, 1870). It will generally be found along with rigid and atheromatous vessels, a well-sustained pulse, and the general systemic indications of chronic Bright's disease. The tortuous temporal artery, so often found under these circumstances, appeals to the eye at once, and the hard and elongated radial artery is equally suggestive to the touch. The persistent high arterial tension has produced a general growth of connective tissue in the arteries, which are in time rendered rigid and brittle by the progress of the morbid change. In consequence of the high blood-pressure and the changes in the arterial coats, apoplexy from rupture of one of the intracranial vessels is very apt to occur. Constantly do we find apoplexy occurring under such circumstances.

But in time the scene changes, and a new set of

conditions is instituted. The general atheromatous changes are more pronounced at points and parts that are the seat of unusual strain. The coronary vessels of the heart become specially affected from the strain to which they are subjected by the recoil of the highly-distended aorta. Springing as they do from the base of the aortic column, they are subjected to the full force of the aortic recoil, and the special distention, added to the general high blood-pressure, produces decided atheromatous changes. This leads to consequent imperfect nutrition, and in time the structure of the hypertrophied heart becomes undermined by molecular necrosis, denominated fatty degeneration of the heart. The different muscular fibrillæ become broken down into a row of fat-cells, in advanced cases. As a consequence of this change, sudden death from asystole is common in the subjects of advanced atheroma. The growing weakness of the decaying heart, however, lessens the liability to arterial rupture, and consequently fatty degeneration has been said to be in so far a preservative lesion.

Attacks of angina pectoris, more or less perfect, are commonly found under these circumstances, and are due to sudden rises of blood-pressure (Lauder Brunton) before which the ventricle falters and not rarely fails. These observations of Brunton, that led to the employment of nitrite of amyl, which dilates the terminal vessels and lowers blood-pressure, mark a new era in medicine, and point the way to the successful palliative treatment of a large class of cases hitherto intractable, because we knew not their pathology and the means of relieving them.

Dr. Moxon, in a remarkable paper on the Nature of Atheroma in the Arteries (*Guy's Hospital Reports*, 1871), gives a plate illustrating the morbid changes. I here copy the letter-press accompanying it.† “Fig. 1. Longitudinal section through a portion of the thoracic aorta, showing a diseased patch. In examining this there are seen, 1, the outer coat swollen, and at the confines of and throughout the diseased patch becoming indistinguishable from it; it blends with the tissue around; 2, the middle coat traced up to the patch, divided into shreds, and spread out in the thickened patch, reappearing in flecks on the section here and there; the change in the middle coat is rather abrupt; 3, the internal coat continued over the patch, rather thickened, pellucid, and bluish in color.

“Fig. 2 shows a part of a thin slice from the section shown in Fig. 1, examined with one-fifth inch objective. *a*. Deep part of the inner coat, composed of fibrillar-looking substances (edges of laminae for the most part). In the part near the middle coat are numerous corpuscles. *b*. The line marking the commencement of the middle coat. This still is composed of elastic fibres, but beneath this, at *c*, corpuscles in great numbers separate the fibres into patches. *d* shows muscular fibre, still persistent; and *e*, elastic fibres, likewise persistent, among crowds of the inflammatory corpuscles; *f*,

* Traube's views will be found in an Inaugural dissertation by Jacob Szostakowski: Ueber atheromatöse Degeneration der Arterien bei Nieren-entzündung, 1869, Berlin.

† The description is such that a vivid impression is created without the aid of the plates.

fatty degeneration of the elastic fibres; and *g*, of the muscle-cells. At *h* a relation of the corpuscles to the vasa vasorum appears to exist."

This gives the microscopic condition of well-developed atheroma very completely, and the relations of the new growth to the normal tissues are well shown.

When this atheromatous change commences in a localized form, at first it appears as white opaque patches of an irregular circular form, single or several aggregated, rising a little from the surface of the inner lining of the vessel, but for some time the surface is smooth. When the atheroma is more general the aorta presents the appearance as if myriads of grains of rice of unusually small size had been placed under the tunica intima. As the disease advances, the whole arterial wall becomes involved, until the aorta feels like a piece of leather. The first or localized change is apt to occur at points exposed to much strain; the more general change involves more or less all the large vessels.

The progress of the atheromatous process is very different in various individuals. Thus, in one the localized spots of atheroma will pass from a semi-fluid mass of round and spindle-shaped cells into calcareous plates, by the deposit of lime salts, which plates may ultimately become loose, and wash off into the blood-stream; or a process of fatty degeneration in the new growth sets in, and then the mass becomes the purée of peas, a collection of fatty corpuscles, débris, and cholesteroline scales, which is apt to wash away piecemeal into the blood-current, leaving the atheromatous ulcer (*geschwür*). Around the aortic valves and the coronary vessels the cell-growth is apt to form excrescences which, becoming infiltrated with lime salts, form little, rough, mortar-like masses, or the valves become themselves stony.

Similar changes go on in the more general form, and the morbid process may result in a general calcification of the diseased vessels, until the arteries are not unlike so many clay tobacco-pipe stems, in which almost all pulsation is lost; or in a condition of general thickening of the arteries, which, however, still preserve a soft feel, and are liable to undergo degeneration; or, again, merely a general hardness with elongation results.

These changes are clinically very interesting, especially in the latter two forms of general atheromatous changes. In those cases where the arterial coats are distinctly thickened, but still soft and fairly compressible, there is also commonly a greasy, degenerate skin, and an arcus senilis, with muddy, blurred outlines, and a cornea cloudy and hazy from the infiltration of fatty corpuscles through its structure. On the other hand, where the arteries are rigidly incompressible and exaggerate the ventricular impulse, with a square-headed pulse-curve and a slow rise, there is usually a dry, even harsh, skin, and either no arcus senilis, or it is sharp, well defined, and of a blue color, with a clear cornea. The difference in these two contrasted conditions is that the one shows a much more marked tendency to degenerative change in the altered vessels, while the other is rather the change almost normal to age.

Clinically and prognostically it is not unimportant to note which form presents itself. The calcified arteries are equally distinct, and mark a degeneration of kind other than fatty. In the intelligent comprehension of the progress of this morbid change, known as the atheromatous process, and, in order to understand the various directions the morbid process may take, we must remember the influence of the environment, the circumstances under which this growth of pathological connective tissue shows itself. The results vary from the scars of Dittrich to the formation of dissecting aneurisms from the atheromatous ulcer, according to the circumstances of each case. When we remember that this morbid process is essentially chronic, extending even to thirty years or more in some cases, we will not feel surprise that the diathesis, and still more the cachexia, of the individual will influence the progress of the growth. Consequently we will find that in a person of good constitution and quiet temperate life the atheromatous change takes a very different course from what it assumes in the intemperate and in those whose constitutions are broken down by syphilis. In the one the process is itself slow in its progress, and free from any tendency to undergo degenerative changes; in the other the morbid change is accelerated, and the new products readily undergo degeneration. Just as in one case the systemic changes are slow, and, as it were, long deferred, while in the other the system ages rapidly and degenerative tendencies are marked, so the chronic morbid process is identically affected.

In the first case atheroma may be marked, and yet be compatible with length of days, that is, with proper care; in the latter case some untoward outcome is to be apprehended. In the latter the liability to rupture in the degenerate arteries is great, especially if the heart be fairly strong, while also there is danger of the heart itself failing in such systems. In the non-degenerative atheroma the risk of rupture from the hypertrophied ventricle bursting the vessels is considerable, but if the individual escape this source of danger to life he often attains a very advanced age ere death takes place from cardiac syncope.

This gradual development of atheromatous change in the arteries, with hypertrophy of the left ventricle, leading to danger of apoplexy from rupture of some of the thin-walled vessels of the brain, and at a later period failure of the heart from fatty degeneration having undermined the hypertrophied heart, form a morbid process well marked, and commonly seen in the stalwart families of the north of England. Oppolzer, in his "Vorlesungen," in the chapter "unter dem atheromatösen Prozesse," gives gout, rheumatism, cancer, alcoholic intemperance, and syphilis as the conditions under which atheroma is most commonly found; but its course in the gouty and rheumatic yeomen, and its course in the broken-down syphilitic drunkards found in town populations, are very different. In the one, the change goes on rather as a chronic scarcely abnormal process; in the other, degenerative decay is almost the rule.

It has been too much the rule hitherto to regard

atheroma as a morbid process which was far beyond the reach of any remedy, curative or palliative. Certainly there is nothing with which we are yet acquainted that can melt the pathological connective tissue out of the arterial walls; the patient cannot be saturated with nitrate of baryta, which, if it would dissolve out the connective tissue, could not undo the changes wrought by its development in the affected vessels. It has been recommended, even in recent works, to use ioduretted frictions to remove the connective tissue out of the valves affected by valvulitis; but this involves, not faith, but credulity. There is no measure which can directly affect the morbid change. But it does not therefore follow that there exist no means by which this change may be affected, and profoundly affected, too, indirectly.

The first matter is to remember the natural history of atheroma, and its connection with persistent high arterial tension; because in lowering that arterial tension lies one most important factor in the treatment. The next is to bear in mind the influence exercised over its progress by any co-existing cachexia or habits. This will suggest the desirability of inducing the drunkard to alter his ways, and of saturating the syphilitic man with mercury and iodide of potassium. In many cases, where mercury alone is too depressant and lowering, it may be combined with iron, as the liquor of the bichloride with the tincture of the muriate of iron, —a combination of incalculable value in anæmic and broken-down syphilitic patients of all ages, enabling the mercurial course to be continued for lengthened periods. All conditions likely to encourage degenerative change in atheromatous vessels must be obviated according to the exigencies of each individual case.

The essential part of the treatment of atheroma is its avoidance as far as possible, and, if its arrest be unattainable, something may be done to delay its progress when it is thoroughly established. This, of course, applies rather to general than to localized atheroma. In order to approach this matter in an intelligent manner, it is necessary to remember the association of a high blood-pressure with the presence of nitrogenized waste in the blood in excess; either from imperfect depuration, or from the unnecessary and excessive consumption of nitrogenized food. The great portion of our urea, uric acid, and the other, the earlier products of nitrogenized waste, are not derived from tissue-disintegration, as is too generally supposed, but from the breaking up of peptones in the liver. By the liver peptones are split up into glycogen and nitrogenized waste. The amount of albuminous matter absolutely required for the daily repair of the tissues is very little. Not only is this known as a scientific fact, but it has been demonstrated in reality by the experience of Abbe Cornaro, and the Miller of Billericay; both instances where high vigor has been maintained for years on a diet containing but small quantities of nitrogen; indeed, a scanty diet altogether. True it is that these men lived, were healthy and hale, on a diet which would be almost starvation to some people: still, their prolonged and vigorous existence proves to a demonstration the small quantities of

nitrogen absolutely required for perfect tissue-repair. The glycogen can just as well be furnished from other than albuminous food. By regulating the diet, then, a decided effect can be produced upon arterial tension. This has been demonstrated by Parkes, of Netley, who found that the blood-pressure fell and the circulation became very calm in soldiers fed upon a strictly non-nitrogenized diet (*Lancet*, May 23 and 30, 1874).

The most important step, then, is to restrict the diet to the absolute needs of the system, to reduce the nitrogen to the lowest minimum compatible with tissue-repair. Every grain of nitrogen above that is unnecessary, and may be distinctly, indeed is, injurious: especially is this the case where there is chronic Bright's disease, and the imperfect action of the kidneys is not supplemented by the dry imperspirable skin so commonly found in such patients. Here the nitrogen must be reduced to the practicable minimum. The high blood-pressure with consequent fullness of the cerebral arteries which follows a highly nitrogenized diet, and gives that sense of energy which we all crave for, is undesirable in persons with commencing atheroma. In them the blood-pressure is high enough at all times, and an increase in it, synchronous with an excess of azotized waste in the blood, produces that cerebral explosiveness known as gouty irascibility, sometimes denominated "pure cursedness." In others of a lymphatic diathesis large quantities of nitrogenized food are indispensable to brain-activity; but then these persons do not suffer from atheroma. The diet should consist of fish, farinaceous foods, vegetables, and, if necessary, fat, in any or all of its forms.

The next step is to remember the form in which waste nitrogenized matter is most permanent, and in which it lingers longest in the system,—viz., as uric acid, free, or as a urate. Potash renders this substance freely soluble, and as urate of potash it readily finds its way out in solution by the various water emunctories of the body. Not only that, but potash, as a muscle-poison, exercises a decided effect upon the circulation, and lowers the blood-pressure, in some persons, most pronouncedly.* Consequently, in the high blood-pressure of a hypertrophied left ventricle and hypertrophied muscular fibre in the arterioles, potash is most serviceable. In persons with a tendency to atheroma, as shown by the sphygmograph long years ere otherwise recognizable, the constant use of potash is desirable; partly as a solvent of uric acid, partly as a vascular depressant. Its latter action may be aided by combining it with the iodide or bromide of potassium, with colchicum, aconite, or veratrum viride, according to the indications of each case. The bowels, too, should be kept freely open, and the practical utility of a mixture of sulphate of magnesia, potassio-tartrate of soda, in infusion of buchu, can only be estimated by those who have tried it. The idea here is to act upon the bowels, and in doing so to remember the connection of excess of lithates with imperfect action in the liver (Thur-

* See Botkin (of St. Petersburg), "*Des Maladies du Cœur*."

chison); the buchu acting pleasantly on the kidneys. This combination is superior to any of the many and excellent mineral waters; especially when well diluted.

Such is the regimen indicated in the early stages of atheroma: it will delay changes that are inaugurated, and check to some extent the progress of the malady. When the latter stages are reached, and heart-failure is threatening, then digitalis or belladonna may be given. But the danger of bursting the degenerate arteries must ever be borne in mind. It is often desirable to join digitalis or squill to the potash in gouty conditions in persons with advanced atheroma and a weak heart, in order to obviate the depressing effects of the potash upon the circulation.

VULSELLUM FOR USING WITH THE ÉCRASEUR.

BY ALBERT H. SMITH, M.D.

IN a recent operation in which I removed the cervix uteri for malignant disease, with the galvano-cautery, I was particularly annoyed at my difficulty in passing the needles for transfixing the cervix. The mass of disease not only occupied the cervix itself, but also encroached upon the surrounding vaginal tissue, and passed up some half an inch into the body of the uterus. The patient had a rather small pelvic entrance; with rigid soft tissues. The passage of needles long enough to secure the whole of the mass to be carried through from one side of the pelvic cavity to the other was a matter of extreme difficulty, the constant wounding of the fingers with the points of the needles, passing through a broken-down cancerous tissue, being unavoidable. I used for the purpose needles with a large curve, straight ones, such as ordinarily used, being absolutely impracticable.

Having in use a large tenaculum, which Mr. Kolbe had made me for this particular case, the suggestion presented itself that if that tenaculum had a shoulder upon its curved angle, over which the wire could be hooked and secured, it would save at least the necessity of one needle; and, if four tenacula could be introduced in the same way, thus constructed, and then joined at their extremities, we would have an instrument of great use in such operations.

I accordingly set to work to devise such an instrument, and Mr. Kolbe has produced it for me. The great difficulty has been in getting a simple mechanism by which to unite the tenacula at their extremities, and, at the same time, enable the operator to tighten them up upon the mass after they are applied.

The accompanying cuts represent the instrument as constructed: A is the tenaculum with its shoulder for the reception of the wire; B the instrument complete, having in its grasp a ball to demonstrate its method of operation.

The four tenacula are made at their lower ends with one surface curved, the other two plane and approaching each other at a right angle, so that when

the four are put together after their insertion into the mass to be removed, they will form a cylinder to pass through a tightly-fitting aperture in the handle, and be secured by a screw-clamp. Thus the relation of the four tenacula will be preserved, and the whole will furnish a powerful vulsellum for traction.

In applying this instrument the tenacula are to be introduced separately, either in the grasp of the fingers, or, in case of very narrow room for working, as in intra-uterine polypus at the fundus uteri, in the grasp of a strong needle-forceps. The ends are then brought together,—adjusted, and passed through the hole in the handle, which is then slipped up upon them as far as it can be carried. Thus a powerful grasp is secured. The wire is then to be placed in the *écraseur*, and the handle of the vulsellum passed through the loop, which may then be carried on until it is passed over the shoulders of the tenacula and retained in position, being then ready for tightening. After the wire has made a sufficient groove for itself in the tissues to retain it in position, if the operator think it more convenient to dispense with the vulsellum it may easily be withdrawn.

I imagine any one who has attempted the removal of large polypi from the cavity of the uterus, even when well pedunculated, and much more when at all sessile in their character, has experienced the great difficulty in having the loop of the *écraseur* sufficiently secured upon one portion of the mass while he draws it around upon the opposite side for tightening it up, it being impossible to introduce more than one hand into the cavity at once. I think this instrument will be found to obviate the difficulty very greatly.

The mechanism for securing the tenacula seems to be defective; but if the instrument proves useful there are, no doubt, many with mechanical genius who can improve upon it.

A BUTCHER named Lerch, residing at Linden, near Hanover, has been condemned to two years' imprisonment for gross negligence. His offence was the selling of a quantity of trichinised meat, which caused the illness of about four hundred persons, and the death of more than fifty.

A COMBINATION OF THE CUTANEOUS AND MUSCULO-CUTANEOUS PLANS OF AMPUTATION.

BY D. HAYES AGNEW, M.D.,

Professor of Surgery in the University of Pennsylvania.

I HAVE recently employed a method of amputation which appears to me to possess advantages worthy of notice. In raising the integument from the deep fascia, after the old plan of the skin-flap, whether circular or oval, a large number of its vessels are necessarily cut, which tends to jeopardize the vitality of the flap. Again, in this operation, the muscles being divided circularly, it is impossible to secure an accurate contact of the surfaces; irregular spaces or cavities between the muscles and flap will remain, in which the discharges collect and interfere with the healing.

If the musculo-cutaneous method be adopted, the skin, from its greater elasticity, retracting more than the muscles, leaves the latter hanging below, thus requiring that they be either abridged with the knife, or tucked and crowded in, so that the stump can be closed. The plan which obviates all these objections is the one to which I refer, and consists in making two oval cuts through the skin, down to the deep fascia, on opposite sides of the limb, raising the integument only a short distance,—say three-quarters of an inch,—and then applying the knife at the junction of the skin-flap and the deep fascia, and cutting the muscles obliquely back to the bone, or bones, as the case may be; or, if transfixation is preferred, thrust the knife through at the angles of the tegumentary wound, and cut from within out. I find, however, the former the more convenient plan. The adjustment between the divided surfaces will be complete.

In the few cases in which I have performed the operation the union has been quick, and the form of the stump perfect. This method is adapted to any part of the fore-arm, arm, or thigh, and even the leg, as its details can be made practical on the posterior part of this portion of the lower extremity.

NOTES OF HOSPITAL PRACTICE.

EPISCOPAL HOSPITAL.

SERVICE OF DR. JOHN ASHHURST.

Reported by G. WINFIELD ZEIGLER, M.D., Resident Physician.

RUPTURE OF THE INTESTINES, FOLLOWED BY PERITONITIS, AND DEATH IN TWENTY-FOUR HOURS, WITH-OUT SIGNS OF EXTERNAL VIOLENCE.

JOHN G., æt. 49, spinner by occupation, was admitted into the surgical ward of the Episcopal Hospital on the evening of July 18, 1875, with the following history and symptoms:

At about 9 A.M. of the same day, he was knocked down and severely kicked on the abdomen by a man with whom he was quarrelling while in a state of intoxication. About twelve hours after the injury he was received into the hospital. I found him lying upon a stretcher, on his right side, with his thighs flexed upon his abdomen and his head flexed upon his neck, crying, and manifesting evidence of most excruciating pain. After his transference to a bed, neither Dr. William H.

Hawkes nor myself could detect any external marks of violence upon his person, excepting a small contusion upon the point of his chin.

His abdomen was very tympanitic and extremely painful to the touch, particularly on the left side. On auscultation, I could detect a gurgling sound on the left side over a line corresponding to that of the descending colon. His pulse was weak and rapid; tongue coated; respirations hurried and labored; skin clammy, and pupils rather dilated. Constant vomiting and severe retching were marked symptoms. He had retention of urine, and stated that he had not evacuated his bladder since early in the morning. There was extended dulness on percussion over the supra-pubic region, and the penis and urethral canal were so firmly contracted as not to admit of the passage of the smallest-sized catheter which I could obtain. The patient, during this time, and even up to the time of death, was in full consciousness.

The treatment when he first came in consisted in the administration of fifteen minims of laudanum; which was immediately rejected by the stomach. I next resorted to the hypodermic injection of one-fourth of a grain of morphia, which dose was repeated in fifteen minutes. A thin flaxseed-meal poultice was placed on the abdomen, and a hot mustard poultice over the epigastric region; hot fomentations were constantly applied over the hypogastric region. About an hour after this plan of treatment had been in operation, the patient began to quiet down, and remarked that he felt much better.

He complained of great thirst; milk and lime-water seemed to allay somewhat the irritability of his stomach. During the night he took about a pint of the mixture. At 11 o'clock P.M., ten minims of laudanum were ordered to be given every two hours until morning. At 2 o'clock the next morning his condition was about the same. I again endeavored to introduce a catheter, but with nearly the same result as before. No sooner, however, had I ceased my efforts than he passed spontaneously fully $\text{f}\bar{\text{z}}\text{xii}$ of urine. At 6 A.M. he complained of increased pain in the lower part of the abdomen. At 8 o'clock the vomiting had increased, and ten grains of subnitrate of bismuth were given. At 10 o'clock his condition was nearly the same, except that the abdominal pain was relieved somewhat. About half an hour afterwards his death occurred by sudden collapse, preceded by stercoraceous vomiting.

The post-mortem, which was made eight hours after death, by Dr. Maury, the coroner's physician, showed that the body was free from external marks of violence, except the small contusion which was observed upon his chin during life. The abdomen was distended and tympanitic; and there was a discharge of stercoraceous matter from the mouth. The peritoneal cavity was filled with an offensive, thin, yellow pus, mixed with a considerable quantity of fecal matter. The intestines were in a high state of congestion; and there was well-marked and extensive peritonitis. By carefully examining the intestines there was discovered in the ileum a small rupture about one-third of an inch in length, through which the contents of the bowels were escaping. The stomach was natural, and the lungs and heart were normal, except that there was some thickening of the tricuspid valves. The liver was slightly enlarged, and of a beautiful pale-yellow color,—a perfect specimen of cirrhosis of that organ. The skull was uninjured, and the brain-substance normal.

SIR WILLIAM WILDE, of Dublin, has been elected an honorary member of the Royal Academy of Science at Upsala, and a corresponding member of the Geographical Society, Berlin.

TRANSLATIONS.

COMMUNICATION BETWEEN THE BLOOD-VESSELS AND THE LYMPHATIC SYSTEM (Tarchanoff: *Centralblatt für Chirurgie*, No. 26, 1875; from *Gaz. Méd.*).—Tarchanoff, after making numerous investigations, has reached conclusions opposed to those of Arnold relative to the existence of a system of canals through which the blood- and lymphatic vessels inter-communicate. He has repeated the experiments of Arnold by first ligating the crural vein of the frog, and then injecting a solution of gelatine, colored with Berlin blue, into the aorta under a pressure of eighty to one hundred millimetres of mercury, and then observing what takes place in the vessels of the membranes between the toes. On the second or third day after ligation the blood-vessels are found dilated and strongly distended with blood; and their walls are at some points ruptured, and the orifices thus caused surrounded by extravasated blood. The matter which is injected makes its exit at the ruptured points, insinuates itself among the blood-corpuscles which are outside of the vessels, and forms a network of communicating stellate figures. Tarchanoff has never observed that the injected materials enter pigment-cells as described by Arnold, nor that there is any direct communication between the two systems of vessels, for the only communication between the matters injected occurs in the meshes of the connective tissue.

If the formation of extravasations of blood is prevented by washing out the blood-vessels with a solution of common salt after the injection, no determinate figures are met with, but only diffused coloration.

The system of canals for the conveyance of the fluids of the body which have been supposed to exist is, then, according to the views of this experimenter, only a series of artificial meshes due to the entrance of the colored injection between the blood-corpuscles.

W. A.

ELECTRO-PUNCTURE OF THE HEART (A. Hénocque: *Centralblatt für Chirurgie*, No. 26, 1875; from *Gaz. Hebdom.*).—After referring to the experiments made upon dogs by Vulpian, Hénocque alludes to the use of faradization of the heart with a view of arousing patients from the syncope of chloroform. Vulpian, by faradization of the heart of dogs, produced a complete cessation of action in that organ. The currents which were employed in these researches, both intermittent and continuous, were of but little intensity, and he concludes that with our present knowledge electro-puncture is too dangerous to be thus employed.

W. A.

BOULIMIA.—Dr. Lubelski reports (*Bull. Gén. de Thérap.*, No. 12, 1875) the case of a woman of 26, who was attacked during the earlier months of married life with certain nervous symptoms, at first supposed to be connected with pregnancy, the menses not having occurred for some time.

At the same time her appetite became insatiable. She ate from twenty to twenty-five pounds of meat per diem. The urine showed neither albumen nor sugar. The patient increased in size rapidly; after a few months she could no longer walk, and weighed about three hundred pounds. A singular toleration for toxic substances was shown. Treatment proved of no avail.

X.

THE INDICATIONS FOR TRANSFUSION.—A discussion on this subject took place at a recent meeting of the Société des Hôpitaux. M. Moutard Martin maintained that in many cases in which cures had been reported after transfusion, the same result would probably have taken place had the operation not been performed. To this

M. Féréol earnestly objected, and added that of the fatal cases reported by himself, life might have been saved in several had transfusion been performed earlier. M. Martin thought that the indications for transfusion should be distinctly stated. M. Buquoy stated that it was generally agreed that the first indication was anæmia from hemorrhage, and that transfusion was contra-indicated when the existence of an organic lesion had brought about constitutional anæmia. Intermediate cases, however, existed where the operation was worthy of trial.

SUDDEN DEATH FROM SYNCOPE SUPERVENING DURING AN OPERATION FOR THORACENTESIS (*Le Mouvement Méd.*, Nos. 27 and 28, 1875).—Dr. Ernest Besnier reports the following case. A stout woman, 43 years of age, was seized with severe pain at the base of the thorax on the right side, accompanied by fever, without expectoration. The appearance indicated the presence of a grave affection. On physical examination, some days later, signs of pleuritic effusion in the right side were observed, dulness, ægophony, etc. Blisters, digitalis, and diuretics were prescribed, and the patient became better. A few days after, she began to get worse again. Further examination showed signs of abundant acute pleuritic effusion, marked but not excessive dyspnoea, respiratory murmur normal everywhere except at the base, where there were fine subcrepitant rhonchi. The general condition was bad; pulse 100. The only symptoms which distinguished the case from an every-day one of pleuritic effusion were the severe pain and general aspect of the patient. Twelve days after the first examination, it was decided to perform thoracentesis. Everything being prepared, a trocar was introduced, and gave exit to a horribly fetid, sanious pus. Some twelve ounces of fluid had passed into the receiving vessel, when attention was suddenly called to the patient, who remained sitting bolt upright, with the eyes open, perfectly pale, and without making the least effort at respiration or displaying any pulsation at the wrist or heart. Every means was used to restore animation, but in vain; the patient was dead. M. Besnier discusses the cause of sudden death in this and similar cases at some length, and concludes that a manifest irritation is produced during thoracentesis in a region which is hyperæsthetic, and that this irritation in cases of exceptional debility may be the starting-point of arrest of the heart's action, an arrest which may become mortal either on account of cardiac disease or debility. M. Besnier alludes to other cases of gangrenous pleurisy, which he considers quite different from, as well as more severe than, the ordinary variety.

X.

CHRONIC AORTITIS.—The following is an abstract of the memoir on this subject read before the Académie des Sciences at a recent meeting by Dr. M. P. Jousset:

1. Chronic aortitis is an affection characterized anatomically by chronic inflammation of the tunics of the aorta. The principal lesions are atheroma, milky and cretaceous patches, thickening and loss of elasticity of the walls, and, finally, dilatation of the artery. The inflammatory character of these lesions has been demonstrated by microscopic examination. The endarterial inflammation may be propagated to the endocardium, and *vice versa*. The lesion in this case constitutes a cardo-aortitis. Concomitant lesions frequently observed are premature ossification of the peripheral arteries and sclerosis of the kidneys.

2. This affection presents itself in two forms: a painful angina pectoris, and a painless variety. The latter alone is discussed by M. Jousset.

3. Chronic aortitis is a common affection. It is continually mistaken for or confounded with an affection of the heart, or rather with an interstitial nephritis.

4. Chronic aortitis sometimes follows acute aortitis. The causes which favor the origin of the latter, alcohol, tobacco, coffee and tea, etc., are the same in both cases. All the patients observed by M. Jousset were gouty or had hemorrhoids, and were all above thirty-five years of age.

5. The principal symptoms are habitual dyspnoea, with occasional attacks of suffocation. The more severe attacks are similar to those of cardiac dyspnoea. The pulse is quickened, becomes small, and may even disappear. Cold sweat, and sometimes syncope, supervene. During the attack the respiration is convulsive and prolonged. Insomnia, loss of strength, and anæmia are other symptoms of aortitis; they lead to cachexia characterized by cedema, albuminous urine, and sub-delirium.

Death results from asphyxia, syncope, or uræmic accidents.

6. The physical signs are various modifications of the aortic sounds, the formation of a plateau in the sphygmographic trace, and increase of aortic percussion-dulness.—*Bull. Gén. de Thérap.*, No. 12, 1875.

X.

NEW METHOD OF TREATMENT OF CEREBRAL RHEUMATISM BY CHLORAL HYDRATE.—M. E. Bouchut remarks on this subject as follows: Cerebral or meningitic rheumatism is a grave form of this affection. Examination of the membranes of the brain reveals considerable venous stasis, with opaline infiltrations of the pia mater caused by numerous leucocytes. Ophthalmoscopic examination shows serous infiltration of the papilla and of the neighboring retina, with dilatation of the retinal veins, which represent similar alterations of the pia mater and brain. Cerebral rheumatism is announced by more or less violent delirium, terminating in coma, and by a sometimes very rapid asphyxia which may cause death in a few hours. In three cases of this kind a cure has been obtained by the aid of chloral hydrate, taken by the mouth, to the extent of forty or eighty grains in one or two doses closely repeated, so as to obtain an immediate relief from the agitation shown by the patient.—*Bull. Gén. de Thérap.*, No. 12, 1875.

X.

IRRITATION OF BOTH PNEUMOGASTRIC NERVES IN MAN (L. v. Thanhofer: *Centralblatt für die Med. Wissenschaften*, 1875, No. 25).—On the 14th and 15th of April of the present year, a pupil of Von Thanhofer permitted experiments to be made upon him, and compression of the right vagus was several times made either by the experimenter or by the patient himself. The pressure was applied by the index-finger of the left side at the inner edge of the sterno-cleido-mastoid muscle, on a line with the thyroid cartilage. Pressure properly applied over the nerve was recognized by the line made by the pencil of a sphygmograph on the right radial artery, and by the patient himself by the occurrence of a prickling sensation to which it gave rise.

Twelve such experiments, in which the pulse-lines were almost identical, showed that the results obtained from experiments on beasts are accurate, and that the pulse and action of the heart became slower, and that the heart indeed can be brought to a state of rest. The truth of the assertion of Ludwig, Hoffa, and others, that irritation of the vagus in dogs causes a diminution of the blood-pressure, was also established. In the experiments in which compression of both nerves was made, the sphygmograph was fastened upon the right arm, while the pressure was made by the thumb and forefinger of the left hand. In some of the experiments the pressure was probably imperfectly exercised, for the pulse-lines were not remarkable, but in the last the line was unique, and the experimenter was much astonished to find his pupil become suddenly speechless while

keeping up a spasmodic pressure upon the pneumogastric nerves. He continued staring with glassy eyes, giving no reply to the inquiries which were made, and it required considerable force to loosen the grasp of his hand upon his bent neck, and, when this was done, some time elapsed before there was a complete return of consciousness. He was at first unable to stand, and when taken into the open air staggered, and said that his head felt very heavy, and as if bound with an iron ring. This sensation of pressure was also felt in the whole body, and especially about the heart, and he had a chill, followed by febrile symptoms.

He retired early, slept soundly, and awoke the next morning with a severe headache, which, however, soon passed off, leaving him once more fit for work, but not at all disposed to renew the experiment, which had given such alarming results.

W. A.

TETANUS CURED BY CHLORAL (L. Papilland: *Centralblatt für Chirurgie*, No. 26, 1875; from *Gaz. Méd.*).—A railroad hand, aged 20 years, received a severe contusion of the last phalanx of one of his fingers, and in a short time was seized with a rigidity of all his muscular system, but which was especially noticeable in the muscles of mastication, to which attacks of convulsions were soon added. A solution of chloral of the strength of eight to two hundred was given in tablespoonful doses every hour until the cessation of the spasmodic seizures.

The patient took altogether seventy-two grammes of chloral, and at the expiration of twenty-two days had entirely recovered, with the exception of a certain amount of rigidity of the left arm. P. concludes that the internal use of the drug will suffice in every case, and rejects the proposition of injecting it into the veins.

W. A.

THERAPEUTIC NOTES.

TREATMENT OF ZOSTER BY INDUCED CURRENTS.—Dr. Fanque recommends the use of induced currents in the treatment of zoster, which is now generally admitted to be of nervous origin.

He recommends that the positive pole be placed upon the vertebral column while the negative pole is placed upon the affected portions of skin.

EMMENAGOGUE PILLS.—Take aloes, 1½ gr.; rue, savin, saffron, of each ¾ gr. To make one pill.

SOLUTION OF SALICYLIC ACID.—As this substance is somewhat insoluble in water, only one part being dissolved in three hundred of the latter, the following formula is useful when a stronger solution may be needed:

Salicylic acid, one part;
Phosphate of sodium, three parts;
Water, one hundred parts.

REDUCTION OF INDOLENT GLANDULAR SWELLINGS.—A writer in the *Irish Hospital Gazette* advises the hypodermic injection of from seven to ten minims of the dilute acetic acid of the British Pharmacopœia.

Indolent enlargements of the cervical glands which disappear slowly or not at all under the use of internal treatment and painting with iodine, are cured in a week or so by this method. Occasionally the effect is to cause atrophy of the enlarged gland, but more frequently suppuration is brought on, lasting for a week or ten days, and ending in a cure.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 7, 1875.

EDITORIAL.

THE UNIVERSITY OF MICHIGAN.

THE medical faculty of this institution are placed in a very delicate position by the fact that some of them are required to aid in the preparation of practitioners of homœopathy. Prof. Sager, in a plain, manly letter, has already tendered his resignation as Dean of the medical faculty. At this distance we are, of course, unable to know exactly how the fermentation is working, but Prof. Sager states that he has been admonished officially and through the medical press "that for the liberty of expressing publicly views at variance with those of the honorable Board of Regents, yet in vindication only of the purity and prosperity of the old school in the Medical Department, I have exposed myself to their displeasure, and rendered myself obnoxious to their censure."

Prof. Sager may be sure of one thing,—that is, that he has the sympathy of his professional brethren, and that sooner or later the school which he has labored so steadfastly to support will reap the harvest of the present sowing. Such is the reward of twenty-five years' labor in medical teaching. Dr. Sager's letter leaves it doubtful whether he intends withdrawing absolutely from the faculty or not; but probably he contemplates so doing. During the present state of dissatisfaction it would hardly appear to be an auspicious time to make any changes in the requirements of students; but at a recent meeting of the Michigan State Medical Society Regent Rynd said that the policy of the regents

was to establish within two years at farthest a full three years' graded course of study and lectures obligatory upon all students graduating in the medical department, and that the requirements for admission into this department would at the same time be made equal to those for admission into the scientific department.

WE have to thank an unknown correspondent for a marked copy of the *Buffalo Courier*, giving an account of the "Buffalo Free Medical and Surgical Dispensing Association." The account is preceded by a large sensation heading, and in it the names of the various specialists, along with their particular callings, are displayed in a manner worthy of Helmbold. Perhaps there never was a more palpable instance of the method in which the profession is as it were devouring itself, or, to speak more correctly, of the injury being wrought by the craze of individuals to get experience and make reputation as specialists. We are told with great satisfaction, by the writer of the account, that the free labor of the Association has enabled the city authorities to reduce the aggregate salaries of district physicians from \$13,000 to \$3000. Is it less a violation of the spirit of the Code of Ethics to steal from a brother practitioner a patient by underhanded means, than to rob him of his salary by doing the same or equivalent work for nothing? If this thing be allowed, it seems to us that the profession will fall below the level of an honest business; since even in commercial circles it is hardly thought honorable to destroy a weaker competitor by selling goods for nothing.

A MIDWIFE—Elizabeth Marsden—is now undergoing penal imprisonment in England for having conveyed puerperal fever to her patients with fatal result. It appears that she was warned that she was spreading the disease, but refused to pay any heed. The London *Lancet* affirms that the general medical profession is much divided in opinion as to whether she "is a martyr or a justly-punished criminal."

RED TAPE AND A STATE RELIGION.—According to the correspondent of the *Pacific Medical Journal*, a woman was recently refused by the Berlin authorities permission to follow the avocation of a prostitute because she had no certificate of confirmation.

ACCORDING to the *Wiener Medizinische Presse*, July 11, cholera at the latest advices (June 17) was epidemic in Damascus, Hamah, and Aleppo.

CORRESPONDENCE.

TRANSFUSION.

UNIVERSITY OF STRASBURG, June 28, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES :

DEAR SIR,—The importance of the subject of transfusion, no less than the frequency with which this operation has been performed of late, and the admirable researches, critical and experimental, which have recently appeared upon the subject, place us in a position, I think, to draw certain conclusions, at least on the physiological side of the question. To give the results of some of these researches is the object of the present communication.

The question which I have in view may be formulated according to the following scheme: Either the blood of one animal is injected into the veins of another of the same species, or it is injected into the veins of an individual belonging to another species. In either case the following conditions are to be taken into consideration.

1. The blood-volume of the animal receiving the injection.

2. The amount of blood injected.

3. The rapidity with which the injection is made.

Investigation has shown that whether the injected blood has or has not been previously defibrinated is a matter of indifference; as is also the fact of the injection having been made into an artery or vein.

The question of greatest importance to the practical physician is whether or not the blood of an animal of a different species may or may not be injected with impunity or advantage. This operation has been so frequently performed of late that at first sight the query would seem hardly worth answering. The results of physiological experiment stand, however, as I shall show, in such decided opposition to the results of practitioners that this must be regarded as the stand-point upon which the entire question turns.

Müller injected the defibrinated blood of one dog into the vascular system of another, measuring the pressure of the circulation meanwhile, by the aid of a manometer placed in the carotid of the recipient.

He observed that during, and for a short time after, the injection, pressure increased in the arterial system, decreasing again, however, in the course of a few minutes to the previous pressure or lower. This may be repeatedly observed in the same animal.

When we increase the volume of blood in an animal above the normal amount, we are not in a position to increase simultaneously the pressure in the arteries; for, as the result of an accommodation as yet not fully understood, the vascular system conforms itself to the increased volume of fluid in so perfect a manner that the newly introduced blood appears after a very short time to be entirely disposed of. The vascular system can, however, only accommodate itself gradually to the increase or diminution of its volume. In a short time after an abstraction of blood which has not been

too excessive, the pressure, which for a time had diminished in the arterial system, is observed again to rise to the point maintained before the blood-letting. Similar researches have been conducted by Panum and Ponfick with particular regard to the subject of transfusion.

And here the important question presents itself, What becomes of the blood thus introduced? Like Müller, these latter investigators give a negative answer to the query; saying, however, that if the transfusion is made with the blood of an animal of the same species, and in a not too rough fashion, the infused blood does not appear in the form of serous or bloody extravasations in the connective tissue or serous membranes.

Among the changes observable in a dog who has been thus injected, are reddening and warmth of the mucous membrane.

When an injection with defibrinated blood has been so managed as to introduce the fluid into the vascular system very hastily, various threatening symptoms appear, and if the injection is too hurried, it fills the right ventricle, and causes extreme tension of the vascular system. Following this, various extravasations in the region of the right ventricle may occur. Extensive extravasation may also take place into the tissue of the lung. Similarly punctate effusions of blood are found in the pericardium and pleura and in the mediastinum, as well as in the intra-vascular structures, the brain and its membranes.

These appearances, observed when the blood is forcibly injected with a syringe, may also be noticed after direct transfusion,—that is, when blood from an artery of one animal is made to flow directly into the vein of another.

If one, however, is careful to regulate the introduction of the blood, the effect is in no way different from that produced by transfusion with defibrinated blood of the same animal. Since, however, the latter method is more easily carried out, and since the amount of the injected blood may be certainly measured and the pressure under which the transfusion is performed can be accurately regulated, which latter cannot be done in direct transfusion, the indirect method is to be preferred.

While the injection into the veins of a healthy animal of blood taken from another individual of the same species exercises little or no influence upon the former, it is far different when transfusion is performed in an anæmic animal. If, for instance, an animal nearly dying from excessive loss of blood is injected with the blood of another individual of the species, the former will be preserved alive with not perceptibly disturbed health. An experiment conducted by Dr. Panum, which illustrates this point, may be here cited.

A half-grown dog was deprived of 200 centimetres of blood, and then had injected 128 centimetres of defibrinated blood from another dog. The defibrinated blood had been preserved in a jar surrounded by ice for twenty-four hours, and, just before the transfusion, was warmed up to a temperature of 36° centigrade (97° Fahr.). After the blood-letting the dog operated upon

became very weak, but recovered entirely after the transfusion, and was as well as ever, no symptoms of any kind being observed.

On the following day 160 centimetres of blood were again taken from this animal, and 150 centimetres of defibrinated blood from another dog were injected. In spite of the fact that the amount of blood transfused into this dog equalled one-third its entire estimated blood-volume, the body-weight remained undiminished. The dog weighed previous to the first transfusion, before a meal, 9920 grammes, afterwards 9950 grammes. On the day of the second transfusion the animal weighed, after eating, 10,450 grammes; on the following day 10,520 grammes before, and 11,200 grammes after, eating; and eighteen days later he weighed, after eating, 12,430 grammes.

This dog was subsequently caused to lose a large portion of his blood in the course of four hours, new defibrinated blood from another dog being simultaneously introduced, so that while 542.5 centimetres of blood were lost, 592 centimetres of defibrinated blood were injected.

If the original blood-volume is reckoned here as one-third of the body-weight, this dog would have had 634 centimetres of blood before the transfusion, so that 93 per cent. of the original blood-volume was exchanged for an equal amount of the blood of another individual of the same species. This dog, which, before the experiment, had weighed 12,430 grammes, weighed the morning after, subsequent to the daily meal, 14,450 grms.

Many other researches prove that the blood-corpuscles of one individual may be so transplanted in another that they continue to act normally, that is, to absorb oxygen constantly from the lungs, and to carry it to the tissues. Here then is the indication for the medicinal use of transfusion. Transfusion, then, is only indicated when a lack of active, working blood-corpuscles is made out. Researches in this particular direction prove that we can neither by this means provide the organism with nourishing material, nor can we by combining blood-letting and the infusion of new blood free the organism from harmful material, which continues, nevertheless, to grow and become reproduced in it.

All this is of value concerning transfusion with the blood of animals of the same species. In order to give, in the shortest possible space, the appearances showing themselves when blood from another species is transfused, I subjoin the following experiment of Ponfick.

A dog had introduced into the jugular vein from the carotid of another animal, during forty-five seconds, 12 per mille of blood of the body-weight of the dog. The following symptoms were observed. During the reception of the blood there was moderate dyspnoea, and with this extreme nausea, but no vomiting, and free defecation. The extremities, particularly the fore-feet, seemed paralyzed. After an hour, bloody-red coloration of conjunctivæ of both eyes; darker in the left. After the animal had somewhat recovered, he was

untied, and observed with the necessary interruptions. There was some red coloration of the urine, fifty-five hours after the operation. During the first day the dog seemed to be doing well, but suddenly collapsed at the end of twenty-eight hours, and appeared moribund. The respiratory movements were superficial, weak, and infrequent. Reflex activity much diminished. The cornea was sometimes quite insensible, at others somewhat sensitive. The pupils were widely dilated. The animal lay powerless on its side; only occasionally was its deathly quiet interrupted by a convulsive movement or a groan. There were, in addition, disturbances of perspiration and circulation, and the dog died at the end of eighty hours from the operation.

Post-mortem examination showed severe renal disease, hemorrhagic effusions in the fundus of the stomach, some pleuritic adhesions, no deposits in the lungs, cornea swollen, and, in addition, hypopyon and keratitis.

Other experiments have resulted similarly, whether the blood of the other animal has been transfused directly or indirectly, with or without previous defibrination. Experiment shows that the serum of one animal dissolves the blood-corpuscles of other species.

From all these experiments it may be concluded that transfusion is indicated only when there are too few actively-working blood-corpuscles present; that transfusion can under no circumstances whatever bring about a cure in constitutional and infectious diseases. In all cases of transfusion among men, human blood should alone be used.

The most valuable contributions to the literature of the subject are the following: "Experimental Contributions to Our Knowledge of Transfusion," Ponfick, *Virchow*, Bd. 62, s. 273; and "Observations on the Transfusion Question," Panum, *Virchow*, Bd. 63, s. 1. Valuable contributions from a physiological stand-point will be found in an abstract of the work done in the Leipsic physiological laboratory under Prof. Ludwig, published in the *Berichte der Sächsischen Academie* for last year.

DR. E. TIEGEL.

NEW YORK, July 23, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THE Woman's Hospital is now closed, according to custom, until the 1st of September; but just before this took place Dr. Thomas had a number of exceedingly interesting cases there. A week after the operation, we had the opportunity of seeing the patient in whom he amputated the cervix uteri for cauliflower excrescence, with the galvano-cautery, as described in a former letter. She had not had the slightest bad symptom, was in capital condition, and will soon be discharged, entirely and permanently cured of the affection, in all probability, or at least as perfectly protected against any return of it as it was possible to make her. The slight burn of the mucous membrane of the labia and vagina by the heat radiated from the

platinum wire was now quite healed, and the parts were altogether normal in appearance.

Among the other cases operated upon during the last few weeks were the following :

Rupture of the perineum through the sphincter ani.—Sims's operation was performed. The mucous membrane was denuded with scissors, first directly over the torn sphincter muscle, and then forward on both sides, over all the surface to be united. The interest of the operation centred in the first two sutures, which were parallel to each other, and passed deep in the tissues entirely around the anus, thus forming an artificial temporary sphincter, or, more correctly, a splint, as Dr. Thomas calls it. It is impossible to close up the anus completely in this way (as some might anticipate), on account of the surface not being denuded all around. The third suture comprehended the tips of the sphincter ani muscle, but was twisted in front of the anus. Four other sutures were then put in anterior to this, as in ordinary cases when the sphincter is not involved. Simple silver wire was used for all the sutures, without any quills, clamps, beads, or other of the contrivances still generally employed in such cases by English gynaecological surgeons.

Ruptured perineum and laceration of the cervix uteri.—Dr. Emmet was the first to call the attention of the profession to the train of evils resulting from lacerations of the cervix, which are so frequent, and so often pass unnoticed, during parturition; and in this case Dr. Thomas performed the operation which he devised for its cure. The patient having been placed on the left side and the Sims speculum introduced, the flaps were separated, and the surfaces which had been lacerated were freely denuded from one lip to the other; a broad undenuded tract, however, being left in the centre, from before backward, which was to form the continuation of the uterine canal to the os. When the hemorrhage is profuse it can be controlled to a great extent by the uterine tourniquet, which is slipped over the cervix and tightened sufficiently high up not to interfere with the operation.

The introduction of the sutures is difficult in these cases, from the great density of the diseased uterine tissue and the mobility of the organ. The first one was passed through the anterior flap, close along the bottom of the fissure, and withdrawn just at the edge of the undenuded strip left to form the canal. It entered again at a similar point in the opposite lip, and made its exit then on the vaginal surface of the posterior flap corresponding with the first point of entrance. Three sutures were inserted on each side, especial care being taken in passing the last one, through the crown of the cervix, with the view of accurately approximating the edges at the os, and along the vaginal surface from this point.

The same plan was followed for securing the uterus as in the operations for vesico-vaginal fistula, ruptured perineum, etc. The needle was armed with a short silk loop, and, after its introduction, the silver wire attached and drawn through to take its place. The ends

of the wire were then seized by a pair of forceps and twisted over the "shield," and finally cut off at half an inch in length and bent over flat, so as to lie close to the vaginal surface. The rupture of the perineum in this case did not involve the sphincter ani, and in the operation for its restoration Dr. Thomas adopted the novel procedure of taking in a portion of the posterior wall of the vagina, which was abnormally redundant, to form part of the perineal body.

Vesico-vaginal fistula.—The patient was a woman of large frame, and a perfect mountain of obesity, weighing probably between two hundred and three hundred pounds. The loss of tissue had been enormous, and, though Dr. Thomas had already performed four operations in the case, a very large fistula still remained. The first had been for the purpose of forming a new urethra (that canal having been quite destroyed), and was entirely successful, though, of course, the urethra would be of no use until the fistula was closed up. The other three operations were undertaken for this purpose, but the opening was so very extensive that no attempt had been made to close it all, except at the last one. This had proved unsuccessful, though the fistula was now only one-half the size it had been formerly.

Dr. Thomas considered this as difficult a case as he had ever seen, and thought it doubtful whether a perfect cure could ever be made. Still, he was willing to make one more attempt, and on the present occasion he was desirous of trying the effect of a "new dodge" which had occurred to him in thinking over the case. This was to secure leaden clamps, by means of silver wire, on each side of the fistula before proceeding to the regular operation for its closure. The failure to unite before had been caused by the huge size of the woman, which produced such tension on the sutures that they always tore out, and the design of the clamps was to remove this from them, as far as possible.

The clamps having been adjusted, after considerable difficulty, on both sides of the fistula, not far from the edges, Dr. Thomas proceeded to denude the surfaces to be united. As before stated, the destruction of tissue had been enormous in this case, the whole base of the bladder having sloughed away, and the cervix uteri having been torn in addition. The capacity of the bladder now was probably not half that of the normal viscus.

The hemorrhage is usually very great in operating in such cases, particularly where it is necessary to cut into the mucous membrane of the bladder, as in the present instance, and Dr. Thomas is of the opinion that it was controlled to a great extent here by the clamps previously secured. Even fatal hemorrhage has been known to occur sometimes in these cases. The operation was tedious on account of the almost insurmountable difficulty of getting at the parts in such a subject, and at least a dozen sutures—possibly as many as fifteen—were necessary on account of the still very large size of the fistula.

The first two were taken in the tissue of the lacerated cervix. Dr. Thomas thought the upper part of the fistula might now unite, but was very skeptical about

the lower portion. Perhaps, however, he said, still another operation in the fall might effectually and permanently close it.

Dr. Emmet, whose experience in these cases is extremely large, had examined the patient and had expressed the opinion that this fistula was probably incurable. If this is so, it will be only the second case of the kind that Dr. Thomas has met with which has baffled his skill.

The report of a case of *atresia vaginae* I shall be obliged to reserve for another letter.

From the weekly reports of the Registrar of Vital Statistics we learn that there were 890 deaths in this city during the week ending Saturday, July 17, and only 454 births, which is certainly not a very gratifying exhibit; though this is the season of the year when the rate of mortality always reaches its maximum.

Still, the death-rate in New York is almost always greater than that of most other large cities in the summer; and this is undoubtedly due to the great fatality of gastro-intestinal diseases among the children of the swarming tenement population of the city. In the week ending July 10, when the number of deaths reached 743, the death-rate here was equal to 37.97 in the 1000 inhabitants yearly; while Philadelphia reported its rate at 27.64; Washington, 27.50; Boston, 20.10; Baltimore, 30.46; Chicago, 30.83; Cincinnati, 30; and Nashville, 32 per 1000. In Richmond, however, it ran up to 44.82. For the week ending July 3, twenty-one large cities of Great Britain reported an average equal to 22 per 1000 yearly death-rate, and Paris reported its rate at 22.09. In New York during the same week the number of deaths was 568, representing an average rate of 27.86; which was less than that of Philadelphia (32.94), Washington (41.25), Baltimore (34.95), or Boston (30.27) for the same. In speaking of the increased mortality here during the past week, the Registrar says it occurred wholly in children under five years of age; 601 of the 890 being of such young children. There were fewer deaths in that portion of the city population which is five years of age and upward than in the average of the year. Of the 359 deaths attributed to diarrhoeal disorders, only seventeen are of persons over five years old. The death-rate in that portion of the whole population which is over five was equal to 16.07 per 1000 annually, while in children under five it was 249.86 per 1000. Young children perish under the influence of continued high temperature in every crowded district in the city, while adult life has in these successive summers suffered a less rate of mortality than in the other portions of the year. During the week ending July 10, 75 cases of diphtheria and 116 cases of smallpox were reported, and during the week ending July 17, 64 cases of diphtheria and 102 of smallpox.

The attention of the Board of Health has been called to the fact that there were 14 deaths from drowning during the week ending July 10, and 32 in the four weeks preceding. As most of the accidents occurred at those sections of the river-sides at which the Health

Department's rescue-apparatus and posted instructions for resuscitating from drowning are not sufficiently near, some lives were no doubt lost for want of the rescue-poles and heaving-lines.

The Fifth Annual Report of the St. Mary's Free Hospital for Sick Children shows that the affairs of that institution—the only child's hospital proper in this city—are in a flourishing condition. The work was inaugurated in 1870, by the Sisters of St. Mary, of the Protestant Episcopal Church, when a house was taken in Fortieth Street, admitting of fifteen beds. This was soon found to be too small, however, and in 1873 the children were removed to their present house in West Thirty-fourth Street, where twenty-six can be accommodated. Here, it was thought, the additional room and more convenient accommodations would prove sufficient for some years to come. The location was good, and the large open garden at the side of the house afforded a healthful breathing-space for such children as were able to go out of doors. During the last two years, however, the work has increased so constantly that a much larger building seems to be a positive necessity, and it is now proposed to purchase the premises already occupied (which have hitherto been rented), and put up a large addition to the house, for which there is ample room on the space adjoining without interfering too much with the children's playground. A number of ladies are in the habit of visiting the hospital from day to day, for the purpose of teaching, reading to, and amusing the children, and who also make, donate, and mend a large quantity of clothing for them. Twenty-five parishes are represented in the Board of Managers, and the managers desire that one or more ladies from every Episcopal church, not only of the city but of the State, should belong to it, in order to make the hospital as general an institution as possible.

The report of the Medical Staff shows that the number of patients in hospital both January 1, 1874, and December 31, 1874, was 21, and that during the year 73 were admitted, and 13 died. The following operations were performed in the same time: exsection of hip, 2; exsection of elbow, 1; for entropion, 1; circumcision, 2; refracture of arm, 1; removal of os calcis, 1; for necrosis of humerus, 2; removal of foreign body from ear, 1.

During the winter there was a slight outbreak of diphtheria, from which one patient died, and a number of children later in the season were attacked with *röthelæa*, or German measles, but there were no fatal cases. The physicians attribute the success attending their treatment in general, in a great degree, to the careful and intelligent nursing received by their little patients. "No one at all conversant with the system of nursing generally adopted in hospitals," say they, "can help being impressed with the superior advantages of the plan pursued here, where the nursing is under the constant and personal supervision of Sisters thoroughly educated as nurses. There is no class of patients who require more constant watching, more gentle attention, and more kindly discipline than do sick children; and no one

can be so well qualified to carry out these requirements as ladies who give themselves to the work solely from a love for the work itself, and for the little ones committed to their care." Drs. Robert Watts and Charles Poore are the attending, and Drs. Flint, Sr., Alonzo Clark, George Peters, and Erskine Mason, the consulting, physicians and surgeons.

Drs. Isaac E. Taylor and Gouverneur Smith having resigned their positions as attending physicians to Bellevue Hospital, Drs. A. B. Crosby and J. P. P. White have been appointed in their places, and Dr. Taylor has been made consulting physician.

Dr. Pallen has been appointed attending surgeon to Charity Hospital in the place of Dr. White, resigned.

PERTINAX.

REVIEWS AND BOOK NOTICES.

LESSONS ON PRESCRIPTION-WRITING AND THE ART OF PRESCRIBING. By W. H. GRIFFITHS, Ph. D., L.R.C.P.E. London, Macmillan & Co.

This little duodecimo of one hundred and fifty pages is agreeably written, and is the most elaborate and satisfactory exposition of the subject on which it treats that we know of. We can heartily recommend it to any one seeking such knowledge as it contains.

TWO THOUSAND YEARS AFTER; OR, A TALK IN A CEMETERY. By JOHN DARBY. Claxton, Remsen & Haffelfinger, Philadelphia.

This little book is not medical in a strict sense of the word; and therefore those readers of the *Times* who value a paragraph only as it affords them immediate additions to their armament for war with disease, may as well skip the present notice. To all thinkers in the profession, the brochure of Dr. Garretson upon a subject which ought to interest every man, and which lies very close to many of the higher disease-problems, must have interest. The writer of the present notice is not a philosopher, and therefore must beg the author's pardon for presuming to criticise his really extraordinary book. We remember, however, to have heard an artist say that he liked to hear the comments of the laity upon his pictures, for, although many ridiculous things were said, yet every now and then a shrewd remark would give him much food for thought.

The book is written in the form of a dialogue, at a supposed reunion of the participants in the immortal controversy that took place on the day of the death of Socrates, concerning the immortality of the soul. It is, as it were, an addendum to the *Phædo* of Plato.

Dr. Garretson is a positivist, holding allegiance to the belief that mind is but the result of organization, and, therefore, cannot be immortal, but, at the same time, claims for man immortality. His chief argument may be summarized as follows:

Man has six senses, so have other animals. Man in this does not differ from a brute; but man has the power of knowing God, and animals have not. Therefore, man differs from the animal in that he possesses what Dr. Garretson calls the sense of *Apprehension*. Further, all men do not use this sense of *Apprehension*, and consequently never know God. To know God, in our author's sense, is to have God dwell in one, and to have God dwell in one is to "grow a soul;" or, in other words, the soul of a man is a part, if the term may be allowed, of God. Some men, refusing to use the sense

of *Apprehension*, never grow a soul, and die, as the beasts die, to rot,—nothing more.

It seems to us very plain where the fallacy is in this argument. It is in the assumption that animals do not have the idea of God. How does Dr. Garretson or any one else, as a philosopher,—*i.e.*, outside of revelation,—know that animals have not the glimmerings of such an idea; that precisely as in them all the mental powers of man are found foreshadowed, so is also his power of conceiving of the idea of God? The author meets this objection in part by pinning his reader on the other horn of the dilemma: if there be no difference between man and animals, then must they share in death a common fate. But, as a philosopher, how does any one know that man is immortal, or that animals are mortal? Even some learned orthodox theologians have believed that animals do share the immortality of man.

Again, granting that man does differ from the brute in the possession of *Apprehension*, Dr. Garretson, to our mind, does not prove that this property of *Apprehension* is not due to the possession of a soul. Let us put the two objections together. Man being organized as animals, if "*Apprehension*" be a mere result of organization, it must, like every other result of organization in man, be shared by the lower animals. Hence they must also have the power of knowing God and growing a soul. Or, on the other hand, if "*Apprehension*" exist in man but not in animals, it cannot be the result of organization, as its existence in man proves that he has a something in himself which is not the result of organization, and which we call soul. Therefore, man may grow—*i.e.*, develop—the soul and become God-like, but the soul that is perfected exists in him from the first.

We do not put this forward as an irrefragable argument, but as one to our thinking, at least, as valid as that of our author. Its logical outcome seems to us in accordance with the Christian idea of the future state, whilst that of the argument of Dr. G. is Buddhism; for if man simply allows himself to have God dwell in him, after the death of the man the God must go whence he came,—*i.e.*, the part that has emanated from the Deity must be absorbed into the Deity, when the casket in which it was confined has been broken.

Dr. Garretson attempts to reconcile his belief with the preservation of the individuality of the man. He says, "Are not the individualities of children as entities, and yet is it to be denied that parent and son are one?" We think any one not a philosopher would not hesitate in his answer to this question. To assert that Adam is the whole human race, past, present, and future, seems scarcely judicious in one who wants to convince ordinary minds.

The perusal of the book before us has confirmed a cherished belief that philosophy, so called, is, like alchemy, an endless search after the unfindable.

God can be known to the race only by manifesting himself. The finite cannot by searching find out the infinite, and the revealing God can only prove to man his Godhead by working miracles,—*i.e.*, by commanding or suspending the ordinary laws of nature. This, if the Scriptures be historically correct, he has done; if they be not true, we have no hope. The belief in the immortality of the soul and the truth of the gospel must, to our thinking, stand or fall together. We see no logical ground midway between the most absolute positivism and the acceptance of the Scriptures.

Almost every decade has its philosopher, and, from Thales to the latest modern, each has been a law to himself. If the reasoning of his fellows has ever changed the belief of a philosopher, we are unaware of it. In science truth is demonstrated, and all men acknowledge it; in philosophy truth cannot be demon-

strated, and each man sets up his own conception,—the outgrowth of the law of his being and his circumstances, which he worships as the truth. Not that we condemn philosophy; far from it. Everything has its uses, and as alchemy brought forth so many valuable discoveries, so has philosophy begotten multitudes of the highest of human thoughts; and the book before us, sharing, as we believe, the common fate of other works of its class, in missing the truth, yet gathers so much of beauty, and throws out so much of suggestion, that we have read it not only with deep interest, but with a resultant of actual good.

GLEANINGS FROM OUR EXCHANGES.

MODUS OPERANDI OF YELLOW-FEVER POISON (*New Orleans Medical and Surgical Journal*, July, 1875).—Dr. George M. Sternberg, Assistant-Surgeon U.S.A., after considering at length the various theories in regard to the causation of yellow fever, concludes that the evidence is sufficiently convincing as to the implication of the sympathetic nervous system in yellow-fever poisoning, but that we have no evidence that blood-changes occur prior to the implication of the sympathetic which marks the outbreak of the disease.

The action of the poison upon the sympathetic seems to be a paralyzing one, causing arrest of function, and producing phenomena similar to those following division of the sympathetic in any part of the body.

Whether the blood is also primarily affected by the poison, or whether the changes in it are all secondary to arrest of the processes of nutrition, secretion, and excretion, may be considered a question still *sub judice*.

The fact, however, that in cases which terminate fatally within a day or two the blood is found to be fluid, the red corpuscles more or less disorganized, and the hæmatin to have stained the tissues of the body, makes it probable that the poison also acts directly upon the blood; but that this action is of the nature of a fermentation, there is not the least evidence.

He suggests galvanization of the sympathetic, or the use of ergot, in the treatment of yellow fever.

CONVULSIONS IN A MALE, ASSOCIATED WITH VESICAL CALCULUS (*The American Practitioner*, July, 1875).—Dr. W. H. Long reports the case of a young man æt. 19, of an excitable, nervous temperament, who, after some slight physical exertion, was suddenly taken with a dull headache.

He was persuaded to lie down, and in a few minutes all the voluntary muscles of his body became rigid; his eyes were fixed with a vacant stare; his breathing was labored, resembling that of a child with false croup. No effort could rouse him to consciousness, and the laryngeal spasm became rapidly worse and the muscular contractions irregular. His body was bent, first on one side, then on the other; sometimes twisted and then bent back, as in tetanus. Occasionally the laryngeal spasm was so great as to suspend respiration entirely, and during the time of this suspension the convulsive movements of the body were extraordinary.

This condition lasted for about six hours, and was succeeded by a quiet natural sleep, on awakening from which he had no recollection of his convulsive attack. These paroxysms continued for several days. He was put upon thirty-grain doses of bromide of potassium three times a day, with citrate of iron and strychnine every six hours. Subsequently, morphia was added, and was given for two weeks. He was then free from trouble for some weeks, when his paroxysms suddenly returned, and about the same time he exhibited symptoms which indicated the passage of a calculus from the left kidney to the bladder. He was then under treat-

ment for about six months, gradually improving, when a stone was discovered in his bladder. Lithotripsy was performed, the fragments were all discharged, and since that time the patient has remained perfectly healthy, is stout and robust, and has had no return of his troubles.

PUERPERAL TETANUS (*Edinburgh Medical Journal*, June, 1875).—Dr. Angus Macdonald reports a case of puerperal tetanic convulsions occurring in a woman æt. 24, about two weeks after her second confinement. He gives the following points as differentiating the case from an ordinary case of eclampsia:

1. The spasms were distinctly *tonic*, and not clonic or mixedly tonic and clonic, as we find in cases of eclampsia.

2. The pupils were somewhat *contracted* and fixed, instead of *dilated* and fixed, as is the ordinary condition in deep eclampsia.

3. The face continued pale during the seizures, instead of becoming congested as in eclampsia.

4. The contractions were very markedly more powerful in the posterior aspect of the body, so as to establish a condition of more or less continuous and complete opisthotonos.

5. The rate of recurrence of the spasms was much more rapid than in any case of eclampsia that he had witnessed, and his experience refers to a large number of cases.

6. The spasms were capable of being excited and intensified by the slightest external stimulus or irritation, such as the touch of the cold hand, or examining any part of the body by tactile manipulation, which is not the case in eclampsia.

7. There was no albuminuria present, which we generally, though not invariably, find in cases of puerperal eclampsia.

On the other hand, the first attack was very sudden; the breathing was stertorous during the individual seizures; the patient was completely unconscious, and these considerations, together with her general aspect, were forcibly suggestive of eclampsia. The preponderance of symptoms, however, tended to prove the existence of a tetanic rather than an eclamptic condition.

IDIOCY (*St. Louis Clinical Record*, July, 1875).—Dr. Alexander B. Shaw reports the case of a family among the members of which idiocy exists to a remarkable degree without there seeming to be on either paternal or maternal side any circumstance pointing to insanity. There is an entire absence on both sides of paralysis, fits, idiocy, tuberculosis, scrofula, syphilis, etc. Consanguinity is denied, and the individual histories of both parents are entirely devoid of any explanatory feature. Four out of five children born during a period of ten years are drivelling idiots.

UTERINE THERMOMETRY (*The St. Louis Medical and Surgical Journal*, July, 1875).—Dr. William Schlesinger has made a series of thermometric measurements to compare the temperature of the healthy non-pregnant uterus (cervix and fundus) with that of the axilla, vagina, and rectum. The instrument used is a thin, slightly-curved, long, bulb thermometer, guarded by a delicate metal case. It must not be introduced with the aid of the speculum, as contact of the cervix with the atmosphere reduces the temperature, and the thermometer must then remain in place a much longer time to indicate the temperature proper of the organ. His results show that the difference between the temperature of vagina and axilla and of uterus and axilla is greater in the non-pregnant than in the pregnant womb, and that the difference between uterus and vagina is about the same in the pregnant and the unimpregnated female.

The practical deduction is that the assertion of former authors who claim that the increase of temperature in the pregnant uterus over that of the vagina was owing to the heat generated by the fœtus, cannot hold good; the same difference of temperature exists between the non-impregnated uterus and vagina.

The author is, however, not prepared to deny the fact that the death of the fœtus in utero will cause a diminution of temperature in the uterine cavity so that it will sink to a level with that of the vagina, and that a correspondence in the temperature of a pregnant uterus and the vagina may indicate the death of the fœtus.

HIRSUTIES GESTATIONIS (*The Medical Record*, July 10, 1875).—Dr. Charles E. Slocum reports the case of a lady, æt. 22, who has borne three children at full term, and suffered one abortion at six or eight weeks. In each gestation a hairy growth on the side of the face and under the chin has uniformly started at the commencement of pregnancy or soon after the cessation of the menses, and continued until childbirth.

Her attention is first called to the parts soon to be covered with hair by a sense of heat and itching, which is allayed but a short time by rubbing, and which continues about three months, with more or less annoyance, and then subsides, to return again after accouchement and remain until the falling of the hair.

The hair is thick-set, fine and soft in texture, straight, and lighter in color than the hair of the head. Its length at childbirth is one to one and a half inches, when its growth apparently stops, and after a period of time varying from four to six months (first child six months, second and third children four to five months), or about the time when the uterine system resumes its catamenial functions, it falls, and the face resumes its normal smoothness.

This hirsute condition during gestation is the only peculiarity in the lady's history. She has uniformly enjoyed health. The menstrual flux was established when she was between thirteen and fourteen years of age, appeared regularly, and was attended with no peculiarity. From the age of fifteen to the time of her marriage, two years later, she suffered slightly from dysmenorrhœa, but not since marriage.

At the time of her abortion the growth of hair on the face was very noticeable, and she became so soon again pregnant that the growth continued until the second conception was completed.

There has been nothing peculiar in the appearance of her children.

Mrs. R. is of medium height and size, with dark-brown hair, hazel eyes, and a fair skin, which becomes of a darker hue when she is in the pregnant state. There was but little nausea following conception, and she was vigorous and able to attend to her household duties at all times. No change or peculiarity other than that already noticed occurs.

MISCELLANY.

HÆMOSTASIS IN SURGERY.—What shall we do with the arteries after surgical operations? It seems now to be a matter of taste; for, to take only the hospitals of London, it will be found that acupressure, torsion, and the ligature, either with silk or catgut, are severally practised in different institutions. No one will, however, complain that various means should be at hand; it is for the surgeon to decide which is the most appropriate in a given case. Much may depend, however, on

whether ischæmia (Esmarch's compression) be used or not. Torsion is a favorite practice in some hospitals; but we have seen abundant secondary hemorrhage after it, and statistics in this respect are wanting. We are, no doubt, far from the time when hot oil was used; and we may boast of a gigantic stride in regard to hæmostasis, though we are apt, now and then, to fall back upon the practice of our ancestors. And here we have Professor Verneuil, of Paris, who is strongly advising *forci-pressure*, which, as the Professor mentions, was first practised by Desault in 1790. It chiefly consists in the application of forceps with continuous pressure, which may be kept up from twenty-four to forty-eight hours without inconveniencing the patient. The instrument has even been known to remain until it became spontaneously detached. The blades may be smooth or toothed, the latter acting more quickly, and, in most cases, successfully. M. Verneuil is convinced that this practice, so long neglected, will not again be so unaccountably abandoned.—*London Lancet*.

DR. PETER, of St. Antoine Hospital, mentions having seen the use of a bath produce most mischievous effects in pelvi-peritonitis. He explains the fact in the following way. On entering the bath, and in order to stride over the edge of it, the woman makes a violent movement, which destroys some of the adhesions established around the internal genital organs, and this rupture becomes the starting-point of a new onset of peritonitis.—*Lancet*.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I am sorry if it has been my mistake that in the discussion on chloral, McRean has been credited with the remarks of Dr. A. F. Shelley. It will be no less alarming to McRean than annoying to Shelley.

Very truly,

H. LEAMAN,

Reporting Sec.

July 26, 1875.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JULY 27, 1875, TO AUGUST 2, 1875, INCLUSIVE.

BROOKE, JOHN, ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 153, A. G. O., July 27, 1875.

ELBREY, F. W., ASSISTANT-SURGEON.—Granted leave of absence for twenty days, and, upon its expiration, assigned to duty at Frankfort, Kentucky. S. O. 106, Department of the South, July 27, 1875.

PAULDING, H. O., ASSISTANT-SURGEON.—Telegraphic instructions of 21st inst. from these Headquarters, directing to proceed, with all possible dispatch, to Fort Randall, D. T., for duty at that Post, confirmed. S. O. 141, Department of Dakota, July 24, 1875.

MAUS, L. M., ASSISTANT-SURGEON.—Assigned to duty at Nashville, Tennessee. S. O. 106, c. s., Department of the South.

TAYLOR, B. D., ASSISTANT-SURGEON.—Assignment at the United States Military Academy revoked, and ordered to report in person to the Commanding General, Department of Dakota, for assignment to duty. S. O. 151, A. G. O., July 24, 1875.

HALL, W. R., ASSISTANT-SURGEON.—Assigned to duty at Fort Gratiot, Michigan. S. O. 144, Military Division of the Atlantic, July 26, 1875.

SHANNON, WILLIAM C., ASSISTANT-SURGEON.—Assigned to duty at Fort Porter, New York. S. O. 144, c. s., Military Division of the Atlantic.

SPENCER, WILLIAM G., ASSISTANT-SURGEON.—Assigned to duty at Lebanon, Kentucky. S. O. 106, c. s., Department of the South.

ROSSON, R. L., ASSISTANT-SURGEON.—Assigned to duty at Fort Monroe, Virginia. S. O. 144, c. s., Military Division of the Atlantic.

SATURDAY, AUGUST 14, 1875.

ORIGINAL COMMUNICATIONS.

A CASE OF POISONING BY STRYCHNIA TREATED WITH CHLORAL HYDRATE AND POTASSIUM BROMIDE.

BY DR. C. BIVINE.

ABOUT midday on the 4th of March last, I was called to see Alice —, domestic, æt. 16, bright and intelligent for her station, of fine physical development, but with a shape of head and expression of countenance indicating deficient mental balance. Strychnia had been taken with suicidal intent, and was in a small bottle, such as manufacturers use to put a drachm of the alkaloid in. It contained "a little in the bottom and what stuck to the sides." She ate no breakfast that morning, and about 8 o'clock A.M. took the bottle, poured it full of water, shook it up, and drank the contents except a few drops. About twenty minutes afterwards she felt "queer all over," her limbs "became numb, and felt as if they were asleep." On attempting to lift a bucket of water, she found she could not do it; would stagger when she tried to walk, and soon after fell off the porch in a severe tetanic spasm. She had one after another, with slightly increasing violence and at irregular intervals from this time on. Owing to the distance at which she lived from my office, and my absence from home when first sent for, it was 12.30 P.M. before I saw her. Soon after taking the poison she confessed what she had done, and was plied with as much sweet milk as she could be made to swallow between the spasms. She was also given a quantity of a solution of sodium bicarb. From the combined effects of the milk and sodium salt she vomited about eleven o'clock (three hours after taking the poison), and again about twelve o'clock; the vomiting seeming to lessen somewhat the severity of the spasms.

When I saw her, she was lying with limbs extended and somewhat rigid; feet everted, head thrown slightly back, neck stiff, countenance pale and anxious, eyes wide open, pupils large, eyeballs oscillating at short intervals, skin moist and cool, pulse 84, full and soft, mind clear; said she had a little pain in the head, but no pain elsewhere, except when the spasms came on. On touching her wrist to feel the pulse, she was thrown into a severe tetanic spasm of the voluntary muscles, worse in the arm touched and in the muscles of the back of the neck. Thinking it probable that the quantity of milk taken had hindered the absorption of the poison, I gave her a dose of tannic acid as an antidote, which she vomited; gave her another dose, which was retained. The spasms became more violent; there was trismus, the jaws closing tightly on the cup whenever she attempted to take anything. General spasms, accompanied by opisthotonos and asphyxia, now came on. I gave her forty grains of chloral hydrate, and re-

peated it in half an hour, soon after which she fell asleep. I left, ordering a repetition of the dose of chloral whenever the spasms should come on again. About 8 o'clock P.M. a messenger reported that she had slept about an hour after I left, had then taken another dose, slept again, and was awake when he left, tolerably comfortable, with some slight convulsions. I gave him a mixture containing forty grains of potass. brom. and ten grains chloral hydrate to the tablespoonful; one tablespoonful to be given every hour till she slept or was perfectly quiet. About midnight I was sent for again, as she was "worse than ever." By the time I arrived, she was sleeping, the third dose of the mixture having quieted her. Her position was natural, breathing regular, 18 per minute; pulse 72, weak, with an occasional intermission in a beat. She slept about three-fourths of an hour; turned over uneasily, groaned in her sleep, and woke up in a violent spasm, accompanied by dangerous asphyxia. Having determined to try the bromide alone, she now got 3ii, in fifteen minutes 3ii more, then thirty grains every fifteen minutes till she had taken 3vi; it seemed, however, to have no effect on the convulsions, which rather increased in violence, and it sickened her stomach so as to cause attempts at vomiting. Gave her forty grains chloral, and in fifteen minutes twenty more; in a few minutes she fell asleep, and slept for four hours.

In the morning she awoke with a slight spasm, but, owing to the necessity of moving her to another room, the convulsions were very much aggravated, and were accompanied by opisthotonos, trismus, and asphyxia, leaving her unconscious for a time; gave her eighty grs. potass. brom. and forty grs. chloral hydrate at a dose, and in half an hour forty grs. potass. brom. and ten of chloral hydrate; after this she was pretty quiet; ordered the dose to be repeated in an hour if she did not sleep; when she had taken the third dose she fell asleep, and slept three hours. From this time the spasms gradually decreased in violence. She took potass. brom. in thirty-grain doses every hour when awake, with chloral at night as a hypnotic, and an occasional dose through the day, when necessary. As the convulsions passed off, the pulse lost its irregularity, remained about 72 per minute, rather weak; pupils became dilated; she had diplopia and confusion of vision, muscular soreness, and paralysis almost complete in the lower limbs, and very decided in all the voluntary muscles; could not put out her tongue; when she was raised up, her head would fall to one side; could not hold anything in her hand. About the middle of the day on the 6th (forty-eight hours after taking the poison) the paralysis began to disappear, leaving muscular soreness and a tired feeling, some dizziness (due to chloral, likely), slight renewal of the spasms, and some nervous symptoms, no doubt increased by the fact that her menses appeared about this time. The spasms were easily controlled by the bromide, and she got no more chloral. From this time forward her recovery was gradual but satisfactory. The convulsions which came on as the paralysis passed

off were light, and lasted about twenty-four hours; when they ceased I stopped all medicine, and, under the use of milk-diet and as perfect quiet as could be obtained, she recovered entirely. She passed her urine once every twenty-four hours; the bowels moved soon after she took the poison; again, naturally, on the 8th, and were regular afterwards. In the first thirty-six hours after taking the poison she got three hundred grains of chloral and about two and a half ounces of the bromide. The chloral weakened her pulse and made her "light-headed" for a few hours after she ceased taking it, and the bromide caused a little irritability of the stomach; but the bad effects of both soon passed off when the remedies were discontinued.

The symptoms in this case may have been prolonged by several circumstances. No doubt the milk and solution of sod. bicarb. which she took hindered absorption. Then she was of a nervous temperament and excitable and amorous disposition. It happened just about the menstrual period. Again, her mental condition was unfortunate, disappointment in love being the cause of her attempted suicide. Moreover, being in a country house in windy March weather, it was impossible to keep her out of draughts of air; she was four miles away from my office, and, being very busy at the time, I could not give her prolonged personal attention; my cautions with regard to giving too much chloral made her nurses too timid in the use of it in my absence.

My observations in this case would lead me to conclude—1, that the bromide alone had no influence on the spasms while they were on the increase, at least not in the doses I gave it in, viz., two doses of $\mathfrak{z}\text{ii}$ each fifteen minutes apart, then thirty grains every fifteen minutes till $\mathfrak{z}\text{ii}$ were taken, when it began to sicken her stomach; but after the spasms began to decline in violence it controlled them decidedly. 2. Chloral alone always gave relief, but it seemed to act only as a hypnotic, and not as a physiological antidote. 3. When the two remedies were given together, a much smaller quantity of each had a more beneficial and lasting effect; forty grains of bromide and from ten to twenty grains of chloral quieted her more than forty grains of chloral or one hundred and twenty grains of bromide given alone.

The uncertainty as to the quantity taken, and the length of time which elapsed before she got medical attention, make it impossible to say positively that the poison would have killed her; at least, however, she took enough to affect her most profoundly, and the remedies acted promptly and beneficially.

TARRYTOWN, MD., June 22, 1875.

A CASE OF SPORADIC CHOLERA—COLLAPSE—BENEFICIAL EFFECTS OF DIGITALIS.

BY JOSEPH V. KELLY, M.D.

I WAS called at 6 o'clock A.M., July 14, 1875, to see J. S. K., aged 35, a carter, who had worked very hard the previous day, exposed to a hot sun. Three hours previous to my visit he had been suddenly attacked with vomiting and purging.

The vomiting was incessant; the stools were numerous and large, and were described by the patient's wife as consisting of "white water," without fecal odor. There were cramps of the belly and of the muscles of the lower and upper extremities. The tongue was cool, the pulse 80, and regular.

He was ordered to be kept quiet, and to have 15 minims of aromatic spirit of ammonia in $\mathfrak{f}\text{z}\text{ii}$ of liq. morph. sulph. every hour.

I was hastily recalled at 9 o'clock A.M., and found the man in a state of collapse. The vomiting and purging had continued, the cramps were intensified, the surface of the body cold and bluish, the eyes sunken, the voice a mere whisper, the features shrunken. The radial pulse beat 110, and was markedly irregular, the volume small; no valvular disease.

I determined on giving digitalis for the failing circulation, and, as time was precious, resolved on giving it hypodermically. One-third of a grain of morphia and ten drops of a reliable tincture of digitalis were dissolved in a syringeful of water, and the whole amount injected into the region of the deltoid muscle. The effect was marked and prompt.

In a few minutes the pulse became more regular and of larger volume, the vomiting, purging, and cramps ceased, and the man sank to sleep. In one and a half hours eight drops more of the digitalis were injected, and afterwards the remedy was given in ten-drop doses every four or six hours by the mouth. Brandy was also given internally as soon as the stomach quieted. In a few hours reaction became evident, the body warmed, the aphonia lessened, and the alarming symptoms subsided. There was no urine passed for twenty-four hours, and then the renal secretion was markedly albuminous.

The digitalis was continued for its diuretic properties. As there was some disposition to diarrhœa, on the 15th one-half grain of morphia was given.

July 16.—Patient doing well; passed one pint of urine, which contains less albumen. No appetite, and great muscular debility. After this the patient did well, and on the 22d of July my attendance ceased.

REMARKS.—I think there cannot be any question that the digitalis, by giving tone to the vascular system, contributed very largely to the patient's recovery; and I submit that the above case illustrates, in a marked degree, the value of digitalis in that class of cases where death by asthenia is apprehended.

4257 MAIN STREET, MANAYUNK.

STERILITY (*The Doctor*, July 1, 1875).—Among the causes of human sterility Dr. Sims mentions the projection of the neck of the uterus into the vagina. If the neck, says he, projects half an inch, sterility is probable; if one inch, it is almost certain; if one inch and a half, it is inevitable. Dr. Giuseppe, of Turin, maintains that in two women out of three the neck of the uterus projects naturally half an inch. The subject is one of importance, and the disparity of opinion merits careful consideration.

NOTES OF HOSPITAL PRACTICE.

GUY'S HOSPITAL, LONDON.

SERVICE OF MR. HOWSE.

Reported by JOHN B. ROBERTS, M.D.

EXCISION OF THE KNEE FOR CHRONIC DISEASE OF THE JOINT—THE ANTISEPTIC METHOD.

THIS woman, aged 27, has at various periods during the last eighteen years suffered with attacks of inflammation of the right knee-joint, which she states began subsequent to variola. Five years since, the inflammation was more severe than previously, and left the joint stiff; but she continued to walk upon the limb until five months ago, when it became so painful that she was unable to move it. The least movement of the limb causes acute pain. There is a certain amount of swelling of the joint, and there is evidently softening of the crucial ligaments, for the tibia and fibula are luxated backward and rotated somewhat outward. If the limbs are placed parallel, the eversion of the foot on the right side is readily seen, and the presence of disease is shown by rubbing the bones forcibly together. The articular cartilages are probably eroded, though there may be no bone absolutely denuded of its covering.

As in a case of this kind there is no use in attempting to cure the disease, and as extreme measures must be adopted, excision of the knee-joint shall be performed, and it shall be done by the antiseptic method. The limb is elevated, and the blood rubbed out towards the trunk with the hands; then the elastic bandage is applied, not all the way from the foot, however, but only around the thigh. The next step is to anoint the integument with carbolized oil, after which a circular incision is made below the patella, with a knife previously dipped in the antiseptic solution. This cut opens the joint, and is followed by a gush of pus and blood.

During all this time the assistants keep up a continuous spray of carbolized water upon the parts, using large atomizers containing a watery solution (1 to 40) of carbolic acid, in order to destroy all germs that may be in the air or upon the hands of the operator.

After the joint has been entered, the flaps are dissected up and the patella removed, when the bones are found covered with granulations and the cartilage is readily peeled off. A saw, with the blade set at an angle, is applied to the posterior surface of the tibia, and a section of the head removed, in one portion of which is found a loose sequestrum. In the head of the tibia there are seen two points of caseous bone, one on each side, which are removed by applying the saw transversely and cutting a triangular groove. The soft tissues around the end of the femur are next divided, and the condyles sawn off; a caseous point similar to those in the head of the tibia being found, it is removed by the gouge and saw. The presence of this disorganized bone proves the propriety of the operation in this case, which in past times would have been left without operative interference and merely placed upon a splint.

Ligatures are now applied to the bleeding arteries by passing a needle, threaded with carbolized gut, through the tissues behind the vessels, tying securely, cutting off the ends, and leaving the knot in the wound. The parts come together nicely after the excision, so as to make a straight limb, and are kept in apposition by gut sutures. Finally, the parts are covered with the dry antiseptic gauze recommended by Mr. Lister, of Edinburgh, and a roller applied to the whole length of the limb.

The removal of this diseased joint will render the patient much more comfortable, and, if all goes well,

will give her a limb which will enable her to walk without any difficulty.

SERVICE OF MR. BRYANT.

A CASE OF DISEASE OF THE TESTICLE—REMOVAL OF THE ORGAN.

This man for three months has had trouble in the left testicle, which is swollen and is the seat of pain of a peculiar dragging character. There is no history of syphilis. The tumor, which of late has been increasing in size, feels heavy, is not translucent, and is hard and tense, though slightly elastic to the touch; at its lower part it feels as though there was a cyst containing thick fluid.

The trouble here might be due to a collection of fluid in the tunica vaginalis, and to syphilitic, cystic, or carcinomatous disease of the testicle itself, but the symptoms and the examination seem to point to the existence of the last rather than the other affections. The pain of which the patient complains in the region of the loins might be attributed to a carcinomatous involvement of the lumbar glands; but it is well not to lay too much stress on this point. He states also that the pain experienced in the part is like that felt when the testicle is squeezed: hence it is reasonable to suppose that the organ, if it be the seat of disease, is not yet entirely destroyed, but retains something of its original character.

The tumor has not heretofore been tapped to determine positively the presence or absence of fluid, because, should there be none, the operation, though trivial in itself, would be followed by a great deal of irritation; but, as the man is now anaesthetized and ready for the operation of castration, should that be deemed necessary, the trocar is plunged into the swelling. There is no fluid found, and the puncture is followed by the escape of a little blood: therefore the removal of the diseased organ shall be proceeded with.

A vertical incision is made through the scrotum, and the diseased testicle, about the size of a goose-egg, turned out through the opening; after which a strong ligature is tied around the spermatic cord, and the mass cut loose. On section, the tumor shows a structure resembling syphilitic gummosus deposits, but we are not prepared to say that it is so. Some portions are soft and disintegrated, while others are hard like enchondroma, as though the soft portion was a later stage where the growth had lost its vitality; and it is very probable that in time it would have been discharged externally. Whatever, however, be the true nature of the disease, it is practically best that it should be removed, and it is now evident that it would not have been advisable to have tapped until the time appointed for extirpation, because severe inflammation would certainly have ensued from plunging the trocar into this softened mass. There is no bleeding from the wound, and no ligatures or dressing will be required, but healing will take place by the ordinary process of granulation.

TRANSLATIONS.

THE LOCALIZATION OF THE VASO-MOTOR CENTRE.—Experimenting upon frogs, Dr. Moritz Nussbaum (*Archiv für die Gesamte Physiologie*) found that when the spinal cord is divided at its upper extremity by the galvano-caustic loop, and the medulla oblongata and brain carefully removed, intense contraction of the arterial walls takes place, observed under the microscope, in the interdigital membrane. This generally occurs within five minutes after the section, and is soon

succeeded by a period of dilatation, lasting about two hours. The nervous system of the frog has now had time to recover from the shock of the operation, and *the rhythmical contractions of the arteries again take place*, as in uninjured animals observed by Schiff and others. That this is produced independently of the action of the general muscular system, is shown by the fact that it occurs also under the same conditions in curarized animals, in which, also, *mechanical, chemical, and electrical irritation of the sensitive nerves are followed by arterial contractions*. After extirpation of the entire central nervous system, the tone of the vessels disappears, the preceding results from irritation of the sensitive nerves are naturally wanting, and the circulation ceases in twenty-four hours at the latest.

Dr. Nussbaum considers that it is therefore certain that the spinal cord, like the medulla oblongata, is individually concerned in the innervation of the vessels, and that the medulla oblongata contains only the upper end of the vaso-motor centre.

W.

NUTRITIVE VALUE OF SUBSTANCES IN BLOOD (Panum: *Centralblatt für die Med. Wissenschaften*, No. 28, 1875; from *Nordiskt. Med. Arkiv*).—In order to obtain the albuminous portions of the blood, that fluid was first diluted and then allowed to coagulate. The coagulum was then pressed out and dried, and from it a powder was procured which can be kept for years without change, and can be used for food. The results of the experiments with regard to its nutritive power by this observer have been tabulated as follows:

1. If dogs are thus fed, 92 per cent. is absorbed, the remaining 8 per cent. being all that can be obtained from the fæces of the animals.

2. The nutritive value of eighty-four grains of the powder, as estimated from the amount of urea excreted during twenty-four hours, is equal to that of three hundred and seventy-five grains of lean meat.

3. When the diet consists largely of matters containing fat and starch in excess, much more carbonic acid and water is excreted than when substances containing albumen are used, more especially powdered blood. In order to keep the ordinary amount of carbonic acid in the body when this powder is employed for food, only half as much carbon has to be given as when a mixed diet of 18 per cent. fat and 72.6 per cent. barley is used.

4. The addition of phosphate of potassium to the food does not influence its value.

5. A dog fed exclusively with barley, fat, water, and common salt for a period of three months can be kept in perfect health. The barley contains all the salts needed to preserve health, but its effect is much increased by the addition of blood-powder.

6. When the albuminous substances of the blood are used as food, the amount of coloring-matter of the blood increases.

7. The amount of saline contents of food which is essential to nutrition is quite small.

W. A.

THE USE OF GUM CLOTH IN THE TREATMENT OF DISEASES OF THE SKIN (Besnier: *Centralblatt für die Med. Wissens.*, No. 27, 1875; from *Bull. Gén. de Thérap.*).—India-rubber cloth was first applied in the treatment of cutaneous affections by Dr. Colson, of Beauvais, and both Hardy and Hebra have since attained satisfactory results from its use. Besnier during the past two years utilized the immense material of the Hôpital Saint-Louis for experiments as to the value of this mode of treatment, and especially prizes gum cloth as a substitute for poultices and the continual bath. He employs for the most part the vulcanized cloth, and only gives the preference to that which is not vulcanized when the

head is to be bandaged or when the patients are delicate children. The cloth must always be clean and entirely dry. Whenever the bandage is changed it must be carefully washed in cold water, spread out, and dried. It must always be applied directly to the diseased skin, without any intervening substance. No pressure must be used in applying it, for the secretions of the skin must be freely allowed to accumulate beneath it. B. casts to one side the gum gloves and stockings, as expensive and unnecessary, but retains the finger-stalls, which, however, he insists should be both long and wide; he also encloses the extremities in gum cloth, and fastens it about them like a sack. On the head he applies caps which are retained in place by their elasticity, and for the trunk shirts and jackets can readily be made. Sometimes this dressing is worn continually, as in pruritus of high grade, but usually only at intervals. As a rule, the gum cloth is used only at night, the patient during the day remaining without any treatment, or being treated with salves, baths, etc. After the bandage is removed, the part to which it has been applied must be carefully dried and powdered with starch or covered with salve. The activity of the cloth depends almost entirely upon its impermeability, which causes an increased cutaneous secretion, and compels the secretions to accumulate upon the skin. The result is to some extent like that attained by the use of a continual bath, as the air is kept from the diseased skin and all friction avoided. He thinks it is extremely improbable that there is any specific action of the sulphur which is contained in the vulcanized rubber. The chief effect is maceration, by which all crusts are speedily removed, as by a poultice. Although to some patients this form of treatment is not applicable, no evil results have been met with even when large surfaces of the body have been thus covered. This treatment is especially indicated when it is desirable to soften the skin, as in eczema, lichen, or pruritus of a severe type. In psoriasis, pemphigus, and syphilis it is more seldom indicated. In the treatment of ichthyosis, eczema rubrum, and moist eruptions of the hairy scalp it seems to give good results.

W. A.

PRÆPUTIAL CALCULI (*Virchow's Archiv*, lxii. 560-565).—In the prepuce of a man aged 52 years, with congenital phimosis, were found fourteen concretions, which together weighed 28.5 grammes. The largest of these, which had made quite a depression in the glans, weighed 12.5 grammes. The calculi had a nucleus which was of at least the size of a pin's head, and in which no layers could be seen, while the exterior portions of the stones were stratified. This external portion consisted of urates of various alkalies, phosphate of calcium and ammonium, phosphites of magnesium, while the nucleus contained a good deal of horny epithelium. In those cases in which no epithelium was detected, it was still thought that the epithelium from the point at which in the fœtus the prepuce and glans join had furnished the nucleus about which the salts from the retained urine deposited themselves. The man had been the father of five children, and finally died of purulent cystitis and nephritis.

W. A.

INVERTED TEMPERATURE IN MILIARY TUBERCULOSIS (Brunniche: *Centralblatt für die Med. Wissens.*, No. 27, 1875; from *Gaz. Hebdom.*).—Among ninety-three cases of phthisis which were observed by Brunnich in 1871 and 1872, and upon which he made post-mortem examinations, a percentage of 59.1 was found with an inverted type of temperature. In twenty-one cases in which miliary tuberculosis did not exist, this inverted type was met with but seven times, a percentage of 33.3.

From these figures Brunnich concludes that this inverted temperature type is a comparatively frequent sign of miliary tuberculosis, and of great diagnostic

value both for the acute and chronic forms. For prognostic purposes it is of extraordinary value, since it sometimes points to an eruption of miliary tubercles, and the consequent grave results. W. A.

ABSORPTION THROUGH THE SKIN (V. Wolkenstein: *Centralblatt für die Med. Wiss.*, No. 26, 1875).—These experiments were for the most part made with the skin of the legs of frogs, which had been stripped from the groin to the toes when the phalanges were disarticulated, so that closed sacs like the fingers of a glove were obtained. The skins of rabbits, etc., were also used, but the hair with which they are covered was found to interfere very seriously with the success of the experiments.

The results of the observations are as follows:

1. The skin is permeable for aqueous solutions when they are not too highly concentrated.
2. An elevation of the temperature of the solution increases the amount of absorption of which the skin is capable, as the absorbent power stands in direct relation to the temperature of the fluid.
3. The skin of young animals of a given species permits absorption with more readiness than that of the old.
4. Hair and wool render absorption more difficult.
5. Certain alkaloids are absorbed by the skin, and give rise to symptoms which characterize the intoxication resulting from them. W. A.

TAYUYA, A NEW ANTI-SYPHILITIC.—M. Stanislas Martin, pharmacist, contributes to the *Bull. Gén. de Thérap.*, No. 12, 1875, an account of this latest addition to the Pharmacopœia. It appears that a M. Ubicini, while travelling in the interior of Brazil, came across a population of negroes who were accustomed to use this remedy with good effect in the cure of syphilis, which was extremely severe among them. M. Stanislas Martin, having received some specimens of the plant from M. Ubicini, has laid them before the Academy of Medicine. In order to assist the labors of the committee of examination appointed by this body, he has published the results of eight experiments made by himself with a view to discover the origin of the bitter taste characteristic of the plant. He has not, however, succeeded in isolating any alkaloid, whether on account of some defect in the method of manipulation or a deficiency in the quantity of the material operated upon.

Further researches enabled him to isolate a green resin, unctuous matter of a citron-yellow color, and brown extractive matter (very bitter, and highly aromatic), tannin, mucilage, glucose (traces), starch, oil, volatile matter, magnesia, alumina, lime, iron, potash, woody matter. The mineral substances are so abundant in this plant that they appear under the form of a white powder when an aqueous decoction acidulated with acetic acid is slightly concentrated. The distilled water of tayuya, and its alcoholic and ethereal tinctures, are highly aromatic. M. Martin does not state what portion of the plant was experimented upon, but promises further details in the coming number of the *Bulletin*. X.

POISONING BY LABURNUM FLOWERS.—I. Clonet contributes to *Le Mouvement Médical*, No. 28, 1875, an article on the poisonous properties of *cytissus laburnum*, from which we abstract the following notes of a case.

A family of Rouen, consisting of seven persons, ate of a batch of fritters containing laburnum flowers, which were used as a flavor on account of their resemblance to those of acacia, which had previously been employed. The flowers alone were used in the dish, the floral peduncles having been rejected. Fifteen

minutes after having eaten the fritters, three of the ladies were seized with a slight feeling of malaise, followed by vomiting, vertigo, and cold sweats succeeded by light fever; then the face became pale, the respiration was accelerated, and the face was expressive of severe pain, augmented from time to time by a succession of spasmodic muscular contractions. After nine hours there ensued transitory languor and somnolence, but this soon passed off, leaving marked insomnia, which lasted through the night.

All these symptoms appeared in five out of the seven persons who had partaken of the fritters, but in various degrees of intensity. One vomited repeatedly during twelve hours, another only two or three times, but in the latter case the other symptoms were more violent. The purgative effect was also very variable. In the case of a vigorous man the symptoms did not supervene until two hours after the repast. In the case of a servant who had eaten the fritters cold, the symptoms did not appear for ten hours. No symptoms of asphyxia were observed in any of these cases.

It results, says M. Clonet, from these facts that the introduction into the organism of about eight grammes of laburnum flowers (the amount taken by each of the persons mentioned) may cause violent emeto-cathartic symptoms, and that consequently the activity of cytisine must be considerable, since eight grammes of the flowers contain only a minute quantity of this substance. The action of cytisine is similar or more severe upon most animals, though upon the horse and rabbit it is said to exercise no effect. X.

COMPRESSION IN HYDARTHROSIS OF THE KNEE.—Compression in the case of hydarthrosis of the knee is usually made by enveloping this joint with cotton wool and then placing a bandage tightly over it. This procedure is defective, since the turns of the bandage become very easily displaced. With a rubber bandage this result need not be feared, but there is here, unfortunately, the inconvenience which constant compression causes the patient, becoming after a time almost intolerable. Struck with these difficulties, M. Guyon has conceived the idea of substituting for this circular compression of the knee the application of the compressing pad of cotton over a gutter which leaves only the anterior portion of the articulation exposed.

The procedure is as follows. The member having been placed in the gutter, successive rectangular folds of cotton batting are placed upon one another until a very considerable thickness is attained.

The circular bandage is passed around the gutter, so that pressure is exercised only upon the anterior portion of the articulation, the posterior and lateral faces being protected by the gutter.

By this means the pain caused by compression of the limb is avoided, and M. Guyon has obtained great success in a number of severe cases of hydarthrosis of the knee.—*La France Méd.*; from *Bull. Gén. de Thérap.*, No. 12, 1875. X.

GOA POWDER IN SKIN-DISEASES.—Dr. Blanc has treated tinea circinata with success by the external administration of goa powder, which destroys the trichophyton with great rapidity. This goa powder, the nature of which is not as yet thoroughly understood, is constituted in great part of chrysophanic acid.

It is employed by simply sprinkling it night and morning over the affected parts, and a cure is obtained by this means in from four to five days. Dr. B. proposes the use of this powder in cases of tinea tonsurans.—*Journal de Thérap.*

M. Gubler has examined specimens of goa powder sent him by M. Limousin. In addition to the usual reactions of chrysophanic acid, of which the powder is

almost entirely composed, he found that, dissolved in ether or alcohol, it imparted an intense emerald-green coloration to the solution. Microscopic examination showed it to be derived from a shrub, holding in its fibres chrysophanic acid, amorphous or crystallized.—*Bull. Gén. de Therap.*, No. 12, 1875.

X.

MODE OF UNION BETWEEN MUSCULAR FIBRES AND TENDONS.—M. Rauvier makes a communication on this subject to the Société de Biologie, in which he shows that the sarcolemma of the individual muscular fibres terminates in a cæcum which is inserted in, and adherent to, a cup or cavity hollowed out in the tendon. When, from any cause, the muscular fibre contracts, it leaves the cæcal end of the sarcolemma adherent to the tendinous capsule, and the intermediate space appears filled with a gelatinous fluid. The attachment between the sarcolemma and the tendon is either molecular or by means of some sort of cement.—*Le Mouvement Médical*, No. 28, 1875.

X.

PLACENTA OF TRIPLETS.—M. Giraud-Teulon recently showed the specimen and read an account of the following case before the Académie de Médecine. A woman thirty years of age gave birth to three living infants, which, moreover, had survived up to the date of the report. The point of greatest interest was in regard to the disposition of the placenta, the three cords, and the three amniotic sacs.

The placenta formed a single mass, into which the three cords were inserted variously, one being inserted in the centre, one at the edge, and the third on the membranes; vascular communications united each of these cords with the other two. There were three distinct amniotic sacs.—*Bull. Gén. de Therap.*, No. 12, 1875.

X.

FISSURE OF THE NECK OF THE BLADDER (*Centralblatt für Chirurgie*, 1875, No. 29).—Spiegelberg calls attention to an affection of which he has seen nothing in medical literature, and which he noticed while making a rapid dilatation of the urethra in a woman who has suffered for a long time from persistent cramps of the bladder. The patient's sufferings followed a confinement, and were not lessened by any of the modes of treatment which were employed. The existence of polypi in the neck of the bladder was suspected, and to investigate the parts an Ellinger's dilator was introduced into the urethra and opened. Intense pain was caused, which soon subsided, but no polypi were found. Marked improvement took place, and in a few days another dilator was employed, followed by an intra-uterine speculum. By means of this a granulating spot about one and a half centimetres in length at the uppermost narrow portion of the urethra was discovered. This did not bleed, and healed in five days under cauterization with the nitrate of silver. A similar case, dating also from a confinement, was seen by the same observer, and recovered with similar treatment. The name "fissure" is given to the affection owing to the great similarity which it bears to the condition of the anus which is so called.

W. A.

TRANSPARENCY OF SOLID TUMORS (Prof. Dr. Lücke: *Centralblatt für Chirurgie*, 1875, No. 29).—Transparency has hitherto been regarded as a property of collections of fluid, and looked upon as of great diagnostic value in the examination of hydrocele and cystic tumors. It has, of course, been observed that the fingers, ears, and other portions of the body transmit light to some extent; but, so far as Prof. L. is aware, notice has not been called to the fact that some tumors possess this

quality; and not long ago he made a false diagnosis of a tumor which he examined. A man presented himself with a tumor of the testicle of the left side, which had existed for several months, and which at the time of examination had attained the size of a goose-egg. It was not painful, and the portion of it which corresponded to the epididymis contained some hard, knotty masses, while in the principal portion of it, which was in front, there was a distinct sense of fluctuation, and complete translucency where the light was of moderate intensity. The diagnosis of tubercle of the testicle with hydrocele was made, and the operation of castration was performed. The operator was surprised to find, instead of the fluid which he expected to meet with, a grayish, cloudy, spongy mass, which under the microscope was found to contain sarcomatous elements. The translucency of the mass was retained after its extirpation, and even after twenty-four hours had passed the presence of this quality was still noted. A tumor of this kind, and with these characteristics, could readily be mistaken for a hydrocele: indeed, without the use of an exploring needle an accurate diagnosis would be impossible.

It is reasonable to suppose that the existence of the same characteristic could be established in tumors of many other kinds, if their position in the body permitted an examination. Among these would be lipomata and myxomata, while in those of a cancerous and adenomatous character it would be absent. Prof. L. does not know whether it would be possible, by more accurate observation as to the character and intensity of the translucency, to arrive at more certainty in diagnosis, but considers the subject worthy of investigation.

W. A.

TRAUMATIC INFLAMMATION OF THE LIVER (A. Ulwerky: *Virchow's Archiv*, Bd. lxxiii. p. 189).—These investigations were made in the laboratory for general pathology in Kiew, and, for the purpose of exciting inflammation, splinters of wood and twisted silk threads were inserted into the livers of frogs, rabbits, and dogs, and by means of wounds diluted solutions of ammonia were injected into the substance of the same organs. The hepatic cells themselves took no active part in the inflammatory process, but were destroyed in the course of retrograde metamorphosis. The pus-cells did not represent products of the division of liver-cells, but were colorless blood-cells which had emigrated. The new growth of connective tissue which is a product of the inflammation probably had the same origin.

THERAPEUTIC NOTES.

GONORRHOEA INJECTION (*The Doctor*, July 1, 1875).—Dr. Haberkom recommends the following, in teaspoonful injections, thrown into the urethra two or three times daily:

R Quiniae sulphatis, gr. vi;
Glycerinae, ʒii;
Acidi sulphurici dil., gtt. v;
Aque, ʒvi.

ITCH OINTMENT (*The Doctor*, July 1, 1875).—Dr. F. W. Clemens warmly recommends the following in cases of itch:

R Acidi arsenici, gr. ii;
Potassii carbonat., gr. x;
Sol. alcohol. saponis, ʒi;
Aque, ʒi.

It is to be rubbed twice daily on the affected parts.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 14, 1875.

EDITORIAL.

THE CASH BASIS.

IN a recent number of the Louisville *Courier-Journal*, a daily paper, is an article of some length, giving an account of and apparently emanating from a meeting of the physicians and surgeons of Oldham County, Kentucky. The chief object of the assembly was to devise means for making patients pay more promptly, or, in other words, the doing away with the present system of long accounts. Concerning the injustice of the present method there can be no difference of opinion: doctors have to pay out with one hand; why should they not receive with the other? We doubt, however, the practicability of completely revolutionizing a rooted custom, although to alter it gradually might be easy. Let a few leading physicians send monthly statements to their better patients, with bills at the end of the quarter, and collect sharply, and much of the difficulty would be overcome. Office-practice and visits to uncertain patients might be paid for upon the cash system: indeed, office-practice in our Eastern cities is already largely upon this basis. A second meeting of the profession is to be held Tuesday, August 17, so as to secure concerted action. Of it the *American Medical Weekly* says, editorially,—

“Will the profession here move as a unit, or will they do as they have often done in regard to a kindred subject (the fee-bill); viz., resolve solemnly, unanimously, etc., etc., that they will do so and so, and then go home and do almost exactly the opposite? There are many

who resolve to charge the rates of the fee-bill, and yet violate the pledge in spirit and in text daily; the honest adherents suffering by their honesty, and the dishonest profiting by their rascality. Will it be thus in this new movement in regard to the cash system? Will the great body resolve so and so again, and then go home and do exactly the opposite?”

Having little faith in concerted action, we believe the profession will do just these things. With us the medical credits during the last few years have been greatly shortened by individual action, and we think that is the only way our Kentucky brethren can save the forty or fifty per cent. of their bills now said to be lost by long credits.

THE “WE”-PRUDE.

MODESTY is ordinarily considered as a virtue, but most men believe it possible for a person to have too much even of genuine modesty for worldly success. This, probably, is true; but many a shipwreck attributed to such an overplus has really occurred upon a very different rock. The diffident, sensitive man is often what he is because he has too little, not too much, of genuine modesty, and of its natural brother,—true humility.

Pride, a fear of making mistakes, a horror of being laughed at, indeed, a form of personal vanity, not rarely make the soil out of which springs the noxious plant excessive diffidence. If a man be really humble, and at the same time be possessed of a little sound sense, he is not over-sensitive to ridicule, and, while willing for effort, accepts its necessary companion, more or less frequent failure.

Modesty whispers, “You are not able for the task; you will fail,” and thereby checks its possessor from unduly taking responsibilities upon himself. It does not, however, paralyze him, since good sense replies to its monitions, “He who makes no mistakes does nothing; if aught devolve on you, do it with all your might, and accept the result, be it good or bad, with humble cheerfulness.”

The greatest cowards are sometimes first in the onset, and the man who acts promptly and boldly often is believed to be conceited, when he really has far more humility than his reserved neighbor who hangs back. Genuine modesty very often hides itself so thoroughly that it is entirely overlooked, but its imitation, prudery, always flaunts itself in the sunlight.

There is a literary affectation to which we wish to-day to call attention, because it is frequent, and because, to our thinking, it is contrary to every canon of good taste and good sense,—is; in fact,

an abomination,—which appears to be especially epidemic among those who contribute to the pages of medical journals. This sin against English, this deflowering of the personal pronoun, is the use of *we* instead of *I*. We object to it because it is in itself bad English; because it is a great promoter of bad English; and because it is a self-glorification rather than a self-abnegation.

First, it is bad English to use a plural pronoun to represent a single person, excepting, of course, the pronoun *you*, which long usage has converted from its original plurality to its present singularity. The editorial *we* is correct, because the writer of the editorial is always *de jure*, and usually *de facto*, speaking for a staff composed of several persons.

Secondly, it is a promoter of bad English. When a person has done anything, or written anything, and means to assert it, it is but a manly, straightforward plan to say, I did so and so. This becomes offensive only when the *I* multiplies itself until it peers out from every corner of the page. There is never any occasion for this endless repetition of the pronoun; indeed, such repetition is, to say the least, inelegant, and is very readily avoided by the use of the passive construction and by other means with which every writer of any skill is familiar. When the author says "I," he is driven by the very nature of the case to avoid the unnecessary use of the pronoun; but "we" seems so impersonal, that nine times out of ten it leads its employer to clothe his ideas in a slipshod, careless, and dowdy style.

Thirdly, it is a self-glorification, rather than a self-abnegation. The use of "we" enables the writer to veil his personality just sufficiently to allow him to be always forcing himself upon his readers without absolutely becoming disgusting. Moreover, where is the modesty of claiming that any one *ego* is equivalent to two? The modern use of the pronoun "you" has, we believe, grown out of an original desire to do homage, precisely as has "mister," and precisely as "lady" and "gentlemen" are now doing.

Not to occupy too much space, we beg, in conclusion, to have no more "we's;" for if sufficient of reasons for abandoning the practice have not been here given, any one having some knowledge of good English can readily furnish others.

THE Government of Great Britain recently requested from the Supreme Medical Council an opinion as to the admission of women to the profession. After a prolonged discussion, the Council

decided that, in their opinion, the study and practice of medicine and surgery by women presented special difficulties, which could not be safely disregarded, but that they were not prepared to say that women ought to be excluded from the profession. As the matter has already been discussed at length in the House of Commons, and as there are both within and without that body energetic men of power urging on the admission of women to the practice of medicine, it is scarcely probable that they will be debarred much longer.

It is stated that Mr. Huxley very rarely attends the meetings of the Royal Commission on Vivisection. The opponents of the practice are, meanwhile, very active, and are appealing through the advertisement columns of the *London Times* for pecuniary aid. The following extract from their advertisement is a curiosity in its way:

"Opponents of the slave-trade agitated not for restriction but abolition. The wrongs perpetrated by man on animals are even more dire than those inflicted by him on his own species. The abolition of slavery was confessedly an act of high Christian philanthropy; and surely it is no less noble or less Christian to stop the sufferings of other helpless creatures of our God.

"The hideous cruelty of dissecting living animals, or inflicting on them, though innocent and defenceless, multitudinous deaths of excruciating and protracted agony, has secretly grown up in this nation,—a nation which for ages past has been nobly distinguished by the courageous and unsanguinary character of its people.

"This moral ulcer has spread widely, and (whether it be or not a dreadful form of insanity) become dangerous and demoralizing to society—a blot on civilization—a stigma on Christianity. The public has little idea what the horrors of vivisection are: its crimes in studied, ingenious, refined, and appalling torture, in wantonness, uselessness, and wickedness, cannot be surpassed in the annals of the world. It therefore calls for extirpation by the Legislature, cruelty being not only the worst of vices in itself, but the most retributive to mankind, more especially when perpetrated by the refined and educated."

It is stated that the Board of Governors of the Presbyterian Hospital of New York City have come to an understanding with their original medical staff. Exactly what has been agreed upon has not yet been made public.

A SCHOOL for nurses is to be opened at Charity Hospital, New York. The course is to be of two years' duration.

THE press; in all civilized communities the almatrater of charlatanism.—*Gazette Hebdomadaire.*

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—While reading your able editorial review of "Circular No. 8," in a late number of your valuable magazine, the thought occurred to me that your remarks were equally applicable to the hospital steward of the army. He is required to be (see Woodward's Hospital Steward's Manual) "of honest and upright character, of temperate habits, and good general intelligence. He must have a competent knowledge of the English language, and be able to write legibly and spell correctly. . . . In addition, he must have sufficient practical knowledge of pharmacy to enable him to take exclusive charge of the dispensary, must be practically acquainted with such points of minor surgery as the application of bandages and dressings, the extraction of teeth, and the application of cups and leeches, and must have such knowledge of cooking as will enable him to superintend efficiently this important branch of hospital service." And, after requiring us to be clerks, druggists, nurses, dentists, and *cooks*, a generous government allows us *thirty dollars a month* as a recompense for our many duties of such different natures and the knowledge required to perform them.

Ordnance sergeants and commissary sergeants, both of whom rank the same as stewards, receive four dollars per month more; and they are but storekeepers, who are not required to have the least professional knowledge.

I claim that the rank of steward is the only non-commissioned one that is strictly professional, and as such should receive a recompense in proportion to the knowledge and experience required to perform the duties of the position.

I also consider that there is no comparison between the responsibility of a steward and other non-commissioned staff officers; the balance of life and death is with him quite as much as the surgeon, for in the careful execution of his superiors' orders rests the recovery of the patients placed under his control.

We, as a corps, have waited long and patiently for justice from the hands of Congress, and many have become discouraged, and by the much better prospects have returned to civil life, and are now in flourishing circumstances. But, instead of doing for us what was our due, Congress has placed us even beneath those with whom we hold military rank.

The navy has recognized the claims of her subordinates in the medical department by giving her first-class apothecaries sixty dollars per month, and an allowance for rations that completely leaves us in the background.

I have enclosed a copy of a bill* prepared by one

of the corps, assisted by the ideas of others, and reviewed and approved by his surgeon. It is only put forward as an idea to be improved upon, with the hope that some one may take an interest to see something done in justice to those who have served faithfully and honestly for so small a return. While the medical department are striving to better their own condition, let them not forget their subordinates, upon whom they must depend for much of their success, by faithful and hearty co-operation.

CADUCEUS.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JUNE 10, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Lipoma.

DR. H. ALLEN presented the specimen, from A. D., aged 45, who noticed a wart-like growth from left popliteal space twenty years ago. The tumor was distinctly pedunculated, and was about the size of a duck-egg. It was without pain; the only annoyance its presence gave the patient arose from its liability to contusion.

Dr. J. E. MEARS recalled a case of tumor which was probably of similar character, also in a woman about sixty years old. In this case the mass took its origin in the left inguinal region, and extended between the thighs as low down as the knees. It was attached by a

ards shall be made; but that thereafter the Secretary of War, upon the recommendation of the Surgeon-General, shall appoint a sufficient number of Hospital Stewards to supply one to each post, and the necessary clerical force for the different headquarters. Such appointments to hold good during the pleasure of the Secretary of War, and with rank next to and after Second Lieutenants.

"SEC. 2. That upon the thirtieth day of June, eighteen hundred and seventy-six, all Hospital Stewards shall be honorably discharged the service of the United States, except those who may be awaiting trial by court-martial. Provided that such of the Stewards now in service as may be recommended by the Surgeon-General, shall receive appointments as Hospital Stewards from the Secretary of War.

"SEC. 3. Be it further enacted: That from the first day of July, eighteen hundred and seventy-six, the monthly pay of Hospital Stewards of the Army, appointed under this Act, shall be fifty dollars; and for every five years' service they shall be paid ten per centum of their monthly pay in addition thereto. Provided that the total amount of such increase for length of service shall in no case exceed forty per centum on the monthly pay established by this Act.

"SEC. 4. And be it further enacted: That for disability contracted in the line of duty, or after thirty years' service, a Hospital Steward may be discharged from active service upon the recommendation of the Surgeon-General, and his name be placed upon the rolls of the army as being so discharged, and shall be entitled to seventy-five per centum of his actual pay at the time of discharge. Provided that he shall be held amenable to all the regulations of the Army and the Articles of War, and that he shall be granted the privilege of selecting his place of residence in the United States, and shall be subject to such orders as may be issued for his guidance.

"SEC. 5. And be it further enacted: That the allowance of quarters, fuel, rations, and clothing for Hospital Stewards of the Army shall be as now fixed by law.

"SEC. 6. That nothing in this Act shall in any way change existing laws relating to Hospital Stewards of the second or third class.

"SEC. 7. That all Acts or parts of Acts inconsistent with this Act are hereby repealed.

* "AN ACT TO FIX THE RANK AND PAY OF HOSPITAL STEWARDS OF THE ARMY.

"SEC. 1. Be it enacted by the Senate and House of Representatives of the United States in Congress assembled: That after the first day of July, eighteen hundred and seventy-six, no more enlistments of Hospital Stew-

pedicle as thick as the wrist, and in its structure appeared dense and in all respects similar to that of Dr. Allen. It had been examined by a number of surgeons, and by some thought to be a large inguinal hernia. A vaginal examination and an exploration of the bladder showed the latter and the uterus to be in proper position.

The specimen was referred to the Committee on Morbid Growths, which reported June 24, 1875, as follows: "The tumor is a simple lipoma, with a denser aggregation of fibrillated tissue towards one end."

Embolism of the middle cerebral artery, with abscess in the fissure of Sylvius.

Dr. MORRIS LONGSTRETH presented the specimen.

Exostosis of lower jaw.

Dr. JOHN ASHHURST, Jr., presented this specimen, which was removed from the lower maxilla of a young girl. The tumor grew from the base of the jaw on the left side, near the angle of the bone, projecting downwards and outwards, and causing quite a marked deformity. The growth, which was pedunculated, was removed without external incision, the operation consisting in freely dissecting off the cheek from the bone, through the mouth, and then severing the attachments of the tumor with strong cutting forceps. The great advantage of this plan of proceeding was that the wound required no dressing, and that there was left no external scar. The exostosis was of the cancellous variety, and, as often happens with these growths, was covered on its external surface with an adventitious bursa.

Solid enlargement of the bursa patella.

Dr. ASHHURST also exhibited this specimen, removed from a young woman who had been suffering from the affection for more than a year. The great density of the tumor rendering it evident that any less radical mode of treatment would be useless, the growth was excised, its careful dissection from the subjacent tissues being much facilitated by the use of Esmarch's bandage. An incision into the mass after its removal showed a cyst-wall nearly half an inch thick, and of almost cartilaginous hardness, the fluid contents of the cyst consisting of a small quantity of a thick synovial-like liquid.

The specimen was referred to the Committee on Morbid Growths, which reported, June 24, 1875, as follows:

"The body removed by Dr. Ashhurst is evidently a proliferating mass of connective tissue springing from the synovial membrane. It is everywhere fibrillated, with the exception of a few points where it is hyaline, and encloses the characteristic mother- and daughter-cells of cartilage."

On the anatomical differences between carcinoma, sarcoma, etc.

Dr. JOHN ASHHURST, Jr., also made a verbal communication upon this subject, prefacing his remarks by saying that after the last meeting of the Society he had found from a conversation with Dr. Tyson that what he had said upon this topic had been misunderstood, and that he thought it right therefore to recur to the subject, and to try to make plain what he considered were the points relied upon by modern pathologists in drawing a distinction between these different forms of morbid growth.

Dr. Ashhurst took, for purposes of comparison, the common fibrous and fibro-cellular tumors (*fibroma*), the fibro-plastic or recurrent fibroid tumor (*spindle-celled sarcoma*), and the scirrhous or hard cancer, which might be considered a typical *carcinoma*. Illustrating his remarks by diagrams drawn upon the blackboard, Dr.

A. said that the fibroma and sarcoma were both tumors of the connective-tissue type, but that in the former the *intercellular substance* was at a maximum, there being very few if any *cells* (connective-tissue corpuscles) to be observed, and these, perhaps, only rendered apparent by the application of acetic acid, while in the latter the cells were at a maximum, and the intercellular substance at a minimum; still, no matter how rich a sarcoma might be in cells, an intercellular substance was invariably present, and with this the cells were in *constant relation*, this being, indeed, the distinctive difference between the sarcoma and the carcinoma. In the latter there was a distinct *stroma*, which might itself be a new formation,—the stroma of encephaloid often contains spindle-shaped cells,—or, as in the case of many scirrhous growths, might be simply the connective tissue of the part in which the carcinomatous material was deposited; but, in either case, in the interstices of the stroma cells were massed together *without any recognizable intercellular substance*.

That this, and not the mere presence of a stroma, was the true and only trustworthy distinction between these two varieties of tumor, was shown by the fact that in the so-called *alveolar sarcoma* there was a distinct stroma which might readily mislead the observer into supposing that he had before him a true carcinoma, and that the real nature of the growth could only be recognized by perceiving that in the alveoli the cells were in constant relation with an intercellular substance. On the other hand, when in any part of a sarcoma the development of cells was so rapid as to cause the disappearance of the intercellular substance, that portion of the growth became truly carcinomatous, and the whole tumor was then called a carcinomatous sarcoma.

In concluding his remarks, Dr. A. said that though fully recognizing the desirability in a scientific point of view of having an accurate anatomical classification of morbid growths, and though acknowledging the great convenience attaching to the use of the term sarcoma, he yet thought that it was too indefinite, in view of the varied significations given to it by different authorities, to merit general adoption by practical surgeons.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held March 11, 1875, the President, Dr. WILLIAM GOODELL, in the chair,

Dr. W. R. D. BLACKWOOD presented a *renal calculus* from a case in his practice. The patient had been recently confined, and ten days after delivery she was seized with the symptoms of the affection, and suffered intensely for thirty-six hours, notwithstanding the use of large doses of morphia hypodermically. The pain was finally controlled by the injections, and the internal use of chloroform. The calculus was of large size, but created no irritation in the bladder, and was voided painlessly at stool. She is now suffering from the descent of a calculus in the left ureter, the first having passed down from the right kidney.

Dr. TYSON, chairman of the committee to whom the calculus was referred, reported that the committee found it composed throughout of oxalate of lime. It is, therefore, a typical mulberry calculus.

Dr. I. S. ESHLEMAN related a case of *placenta previa*. He also referred to a case which he had presented to the Society a few months ago, published in the *Medical Times* of the 20th of March, in which he had delivered the mother safely of a living child, giv-

ing the mode of management which he has for several years practised. He prefers the obstetrical forceps (head first) to turning. He uses them to arrest the hemorrhage, dilate the os uteri, and deliver.

The patient was Mrs. M., residing near Roxborough, seven miles distant, in the suburbs of the city. She became enceinte in the first week of August last. About four weeks after, on a Tuesday, she experienced a slight hemorrhage. After four months had passed she had a second hemorrhage, coming on, as the first, on a Tuesday. Subsequently, there was a flow of blood on every Tuesday for five weeks, and after this on every Friday for three weeks; then every Saturday for two weeks a free hemorrhage occurred. On the following Thursday a more severe flow occurred, lasting until the following day at 2 P.M. On the following Thursday morning, March 4, 1875, the most copious hemorrhage began, within one week of the seventh month. In this condition her husband brought her into the city to her mother's house, in a large close Germantown wagon, which ran on the Ridge Avenue railway, a fresh fall of snow having smoothed the way in some measure. He (Dr. E.) then saw her for the first time. The friends exhibited a bushel-bag filled with well-stained cloths, the result of that morning's hemorrhage. Her face was pale and pinched, and the skin shrivelled as in cholera. Brandy and milk were freely administered. Examination per vaginam verified the diagnosis of placenta prævia. The os was half an inch in length, but soft, and the index-finger could be pressed through the neck and into a crevice in the placenta which dipped down in a line with the os to its fetal surface. The walls of this crevice were continuous with those of the uterus, no separation of the placenta being observed. Exploration exterior to the os gave the sensation of placenta as far as the finger could reach. It was his impression that he had to deal with a case of central implantation of the placenta. No hemorrhage was provoked by this examination carefully made. From beginning to end, the mother experienced no labor-pains. He had never known labor-pains, that could be felt by the mother as such, in placenta prævia, nor in detached placenta, but instead had observed a continuous contraction, which he regarded as an effort of nature to prevent hemorrhage. But even this is not usually felt by the mother after much loss of blood. A little more time was considered proper in order to replenish the supply of blood and obtain reaction. In this condition immediate hemorrhage was not to be apprehended: so he went home for instruments. A convulsion caused him to be hastily summoned to the house again, taking with him such instruments as would be likely to be needed in case tamponing should be deemed necessary; also, Barnes's and Molesworth's dilators. (Ice-cold douches were ordered to be in readiness previously.) The convulsion was over when he arrived. It had lasted for about ten minutes. A half-drachm of chloral was given immediately. He had used it in all forms of convulsions, since its discovery, beginning with the infant at birth; in the puerperal variety he had never known it to fail, and in general its use had been most satisfactory. (He had recently dismissed himself from a consultation in a mild case of post-partum puerperal convulsions because the doctor in attendance would not consent to the administration of chloral, and he (Dr. E.) would not share the responsibility unless it should be given. A few days revealed crape at the door of the young husband's beautiful mansion.) If blood-letting alone were sufficient, why did this patient (Mrs. M.) have a convulsion when she was exhausted from loss of blood? Examination showed that during the spasm she had lost a few ounces from slight additional separation of the placenta around the os, but the flow had ceased. The os was now more relaxed or less

bound by the placenta. Symptoms of return of convulsions called for twenty grains of chloral additional. He also administered ergot, to insure contraction after delivery. Brandy and milk were given freely. To tampon properly would so distend the vagina as to complete the separation of the placenta, which he desired to avoid, as he had resolved to deliver through the placenta, knowing that at the first indication of recurring hemorrhage he could at once proceed with his fingers or his dilators to tampon and dilate at the same time sufficiently to admit the forceps. Here he watched the case very closely for two hours. During this time her condition improved, while the os had grown soft and dilatable. Depleted as she was, efficient labor-pains were not to be expected, and feeble pains could now produce only gradual separation of the placenta, and hemorrhage. To introduce the hand and turn would usually require forcible dilatation of the os to a diameter of about three inches. This would produce almost or perhaps altogether complete separation of the placenta, and do great violence to the os, and be followed by the often fatal operation of turning the child, which places its long diameter in the short diameter of the uterus. It would be to witness great agony and hear the suffering mother plead for death. The woman was too weak to indicate an anæsthetic. The uterus now showed signs of firmer contractions or a firmer condition of the tumor when handled. Ergot was doing all that could be expected in her enfeebled condition. There was reason to hope that the organ would now contract after delivery, if not paralyzed by the operation of turning, and if delivered with the forceps by intermittent efforts in imitation of nature. Gentle pressure upon the abdomen was made by my assistant, while one finger and afterwards two were easily passed into the os. The speculum forceps were next entered and passed up into the fissure found in the placenta, which carried their points onwards against its inner foetal surface, when, with gentle pressure and a boring motion, they entered the amniotic sac, from which the water flowed. The handles were forcibly separated, making an aperture of about two inches in the placenta. This began at the insertion of the cord, immediately over the os, and extended towards the mother's left. The obstetrical forceps were now employed, but, owing to this opening in the placenta, extending to the mother's left, the second or right-hand blade was displaced in that direction, falling also upon the left side of the child's head. He withdrew the instrument, and, applying first the right-hand or female blade, and following it with the other, grasped the head in the first position. He was able, in the attenuated condition of the patient's form, to rock the forceps from side to side, and, by placing his hand upon the abdomen, verify their proper application. He immediately brought the head down into the pelvis firmly upon the placenta and the os uteri.

No considerable hemorrhage attended this operation, which was done in about the time consumed in relating it, but without undue haste. Here he felt that the case was under his control, so far as the safe delivery of the mother was concerned. No further hemorrhage was possible, and if the os yielded to the equable pressure upon the placenta, delivery would be readily effected. The child was small (premature, as usual). If the os did not yield, moderate pressure upon the interposed placenta must arrest hemorrhage, and prevent further separation of the placenta than necessary to admit of dilatation. The child had exhibited no signs of life for twelve hours. Failure to secure uterine contraction after delivery might complicate matters. But traction upon the forceps caused the womb to respond, as shown by hardening of the tumor. The case was conducted in imitation of natural labor, as every forceps case should be. There can be no excuse (in most instances)

for rupturing the perineum with the forceps on the child's head. On the contrary, the instrument may be made supporters of the perineum by restraining the expulsive force of the uterus. If necessary, between pains, bilateral incisions into the labia, however slight, will magically relieve an unyielding vulva, and the obstetrician will be puzzled to find them after the child is born. The child was delivered in about thirty minutes; it could have been effected in ten had it been alive; but, being under seven months, there would in that case have been small chance of its living. No perceptible hemorrhage followed, and the uterus closed softly upon the hand inserted within its cavity. The placenta remained adherent in its entire circle. This his assistant was called to witness. Its centre was extensively separated and crushed, a portion being pressed off by, and descending with, the child's head. External pressure and grasping with the hand consolidated the uterus as the placenta escaped from its cavity. The membranes were unbroken, and contained some fluid. The aperture through which the child was delivered extended from the insertion of the cord to the edge of the placenta, and was about three inches in length, as if too small for the passage of the child.

The mother uttered no complaint during all this time, and said she did not have a pain. She had given birth to four children previously; none so easy.

He prefers the forceps to turning in these cases. He finds, usually, a free edge of the placenta, and, after hemorrhage, a dilatable os, so that when able to introduce two fingers the forceps can be applied; and, having grasped the head, sufficient pressure can be made upon the placenta to control hemorrhage, and at the same time dilate the os and effect a much earlier delivery, upon which, in a great measure, the lives of mother and child may depend. His prejudice against the operation of turning has not been lessened by the very great difficulty that he experienced, since treating this case, in turning a large child on account of a narrow conjugate diameter of the pelvis, which procedure was followed by an attack of metritis, from which the patient almost lost her life.

Dr. NEBINGER asked how far pregnancy had advanced (in the placenta-prævia case).

Dr. ESHLEMAN. Six and three-fourths months.

Dr. NEBINGER. Do you say you never knew decided labor-pains in placenta prævia?

Dr. ESHLEMAN answered that he had never witnessed ordinary labor-pains, and that his patients had always declared they did not feel any, even though the uterus felt hard. But when traction is made upon the forceps, the womb contracts freely, even though the woman might be exhausted by hemorrhage.

Dr. NEBINGER asked whether this treatment would be practised at all periods of gestation.

Dr. ESHLEMAN said he had never employed the forceps earlier than the sixth month. Whenever he obtains dilatation of one and a half inches, and finds the free edge, or thinnest portion, of the placenta, towards which the separation inclines, he completes the track and applies the forceps, whether the os be rigid or soft, and then brings the head to bear upon the placenta. This done, he finds the hemorrhage cease. He has never torn an os.

Dr. NEBINGER asked whether he would use this treatment at eight or nine months; and how much blood had been lost by this course.

Dr. ESHLEMAN replied that in the former case, which he saw early, during the first free hemorrhage, at the eighth month, probably from a pint to a quart had escaped prior to the application of the forceps, but not an ounce afterwards. The child was resuscitated, and lived. The mother showed no unusual exhaustion, and did well. In the latter case, probably four ounces had been lost

during the convulsions, but none during the delivery. This woman had lost a pint or more of blood suddenly every week for three months without using any means to arrest the flow.

Dr. NEBINGER asked whether, supposing that at eight and a half months the hemorrhage being so profuse that exhaustion was positive, and the bleeding continuing, he would then apply this treatment.

Dr. ESHLEMAN did not remember ever treating a case advanced to eight and a half months. Unless the placenta be located very partially over the os, labor will come on earlier. Nor does he think hemorrhage would continue with exhaustion. He never so found it. He would proceed, applying the forceps if the os would admit, during hemorrhage, as he could arrest most quickly and completely prevent future hemorrhage by this means. Delivery may be accomplished very slowly after the application of the forceps, giving ergot and stimulants ample time to act in cases of great exhaustion. But the child would be likely to perish under such circumstances. Tamponing (with the delay incident to it) lessens the child's chances for life.

He said that turning is acknowledged to be a hazardous practice to the mother as well as to the child. Statistics amply prove this. He does not feel safe in relying upon the tampon, so rapidly does the vagina expand, dilating the os, and separating unnecessarily the placenta. The tampon also induces heat and inflammation of the parts.

Dr. WELCH asked Dr. Eshleman whether he tamponed before dilatation.

Dr. ESHLEMAN said such had been his practice, but he did not in the last two cases. The former he had once delivered, having a dilatation of one and a half inches. The latter having just experienced a hemorrhage, he did not apprehend another very soon; nor should he have had a recurrence but for the occurrence of the convulsions, which separated a portion of the placenta. He sat down prepared to operate with the first symptom of reaction or hemorrhage. He waited two hours, and delivered without loss of blood. In answer to Dr. Goodell, Dr. Eshleman said he had always found trouble in using dilators, in keeping them in proper place. Had hemorrhage occurred in the latter case before he obtained sufficient dilatation or a dilatable condition, he would then have tamponed or dilated, but not to more than a two-inch diameter, for fear of separating the placenta, when he would have applied the forceps to compress the placenta, dilate the os, and deliver.

Dr. NEBINGER remarked that the practice of Dr. E. was new to him; that it might be good practice, and better than that which he had pursued in placenta prævia, yet he felt that he would prefer to depend upon a practice which he had found useful, and which had the endorsement of the highest authority, both at home and abroad. In illustration of the practice referred to, he would briefly narrate a case which occurred in his practice.

Mrs. —, residing in the Neck, or rural portion of the southern section of the city, was seized with a slight hemorrhage from the uterus on a Friday. She was in the ninth month of her pregnancy. He was sent for; when he reached her, she was up and moving about her house, the hemorrhage having been but slight, sufficient only to alarm because of its being unusual, and at a time anterior to the period when she expected her term to expire.

The patient was directed to go to bed. An examination was instituted, and placenta prævia diagnosed. The vagina was well tamponed with small pieces of sponge, and the lady directed to keep her bed. The following day, Saturday, she was visited, and the sponge removed. There had been but very little hem-

orrhage, not sufficient to soil all the pieces of sponge placed in the vagina. The os uteri had slightly dilated, say to about the extent of an inch. The vagina was again packed with small pieces of clean sponge, and the patient directed to remain in bed.

She was visited on Sunday morning, and the sponge removed. There had not been anything more than a very slight leakage, not more than there had been during the previous twenty-four hours. A slight increase in the dilatation of the os uteri was manifest. Fearing that the further continuance of the sponge might produce some vaginal irritation, he determined not to again pack the vagina, but instructed the nurse that in the event of hemorrhage she should force as many pieces of sponge into the vagina as possible, and at once dispatch a messenger for him. About 5 o'clock on Sunday afternoon he was summoned to visit his patient. Her residence was at least two miles from his home. He responded promptly to the call. When he reached the bedside of the lady, he found that the nurse had in the matter of the introduction of the sponge so limitedly complied with his directions that she had not effectively accomplished anything. The hemorrhage had been very great, and was still going on. The lady's face was blanched, pulse very small, skin damp, and the whole aspect such as to excite great fear for her safety. Whisky, in positive quantities, at short intervals, was administered, the vagina cleared and well packed with sponge. Milk-punch was in due season substituted for the whisky, and as much administered as the patient could take without producing sickness at the stomach. The lady reacted slowly. After the reaction was established, she complained of labor-pains. The pains increasing in severity, and the intervals between them diminishing, the doctor recognized that the period was approaching when it would be proper to effect the delivery of the babe. Feeling that the interests of the patient and his own professional interest required that he should summon to his assistance and counsel a professional brother, he, at 2 o'clock on Monday morning, sent an invitation to Dr. Ellerslie Wallace to come to his assistance, to share with him alike the responsibilities and the toil. The doctor very promptly responded. When Dr. Wallace arrived, it was manifest that expulsive pains were present by the disposition the patient had to bear down, and by the distention of the vulva by the forcing down of the sponge. The use of the milk-punch was continued, and the administration of ergot was commenced to increase the expulsive force of the uterus, so that when the delivery of the child should be effected there might be such strong and prompt contraction of the uterus that there would not be post-partum hemorrhage. At 5 o'clock, about two hours after Dr. Wallace's arrival, the conditions were such as caused the doctors to determine to remove the sponge from the vagina, and, if practicable, deliver. Upon the removal of the sponge Dr. N. said he found that the os uteri was well dilated, and the placenta entirely covered it. Passing the right hand between the placenta and the uterus, it was then passed into the uterus until the feet of the babe were reached; these were then grasped, and version commenced.

The delivery of the child was effected without any delay from resisting soft parts, or from the head assuming an abnormal position in the pelvis. The expulsion of the placenta followed immediately the delivery of the head. The uterus contracted promptly and forcibly. The amount of blood lost did not exceed four ounces. The child was dead. The mother made as good and prompt recovery as could have been expected under the circumstances of her exhausting and dangerous labor.

Dr. Nebinger said he felt confident that if he had

attempted delivery by the use of the forceps, as described by Dr. E., or in any other manner, before his patient had reacted, he would not have achieved the good results he did. He felt that the indications, the urgent indications, were the arrest of the hemorrhage, the establishment of reaction, the holding up of the vital forces until delivery was effected, and the prevention of post-partum hemorrhage. These indications were met, and, as their result, a safe delivery of the lady. To him, the doctor said, the practice appeared good, and upon it he had relied in the other cases of placenta prævia which had occurred in his practice, which were, however, not many, as he could count upon the ends of four fingers all his own cases.

Something, Dr. N. remarked, had been said of the inefficiency of the tampon. He feared that where the tampon had not been used with good results, it might have been either because of the imperfect manner in which it was applied, or because of the material used. He gave the preference to sponge. To effectually tampon, he had found it necessary to reduce the sponge to small pieces, and to introduce them one by one, not merely until the os externum, or vulva, be, as it were, occluded, but until the vagina is most thoroughly and positively packed. Such a tampon had never failed to serve him well, and such a tampon he had employed with success over and over again, in more instances than he would name, to arrest hemorrhage in cases of abortion; and now, looking back upon the past, he was gratified with his experience, and felt that its results were such as to justify him in having recourse to the same practice in the future.

Dr. WILLIAM T. TAYLOR said,—“I have had but few cases of placenta prævia, but I can call to mind one in which there was a very profuse hemorrhage, so as to render the patient very pallid, her pulse being very weak and small. As the os was covered by the placenta, I tamponed her with rags, which arrested the flow, except some slight oozing. Having given stimulants and waited for an hour or more, the pains had increased so much that the tampon was removed. The os being well dilated, a full dose of wine of ergot was given, and, having passed my hand between the edge of the placenta and the uterus, I brought down the feet and body of a small child; in a few minutes the arms and head were delivered. It was quite exhausted, but soon cried vigorously. I mention this case because the child lived.”

REVIEWS AND BOOK NOTICES.

REST IN THE TREATMENT OF NERVOUS DISEASES. By S. WEIR MITCHELL, M.D. G. F. Putnam & Sons, New York.

This brochure constitutes one of the series of American clinical lectures now being published under the editorial management of Dr. Seguin. We have read it with very great satisfaction, and when we say that it is one of the best contributions Dr. Mitchell has made to practical medicine, we award it, in our opinion, the highest praise. We find only one fault: too much is attempted in a small space. When the author returns from his absence abroad, we trust that he will expand it into a moderate volume. In the mean while, we say to our readers, Read this lecture, and you will find its therapeutic suggestions invaluable.

THE ABUSE OF MATERNITY. By ELIZABETH EDSON EVANS. J. B. Lippincott & Co., Philadelphia, 1875.

This little book is upon a subject which has been much written about of late. It owes its chief interest to the extremely feminine point of view which its author

holds, and to the fact that she is seemingly possessed of more common sense than most of the writers upon such subjects, in that she has a section "On the Abuse of Maternity through its Unwise Acceptance." Her method of escaping the logical results of the opinion that it is not at all times the duty of woman to breed as often as possible, is certainly original and amusing. It is sufficiently indicated in this sentence, "Again, the poor ought not to marry." Although such utterances as this are, to our thinking, practically absurd, yet we feel like praising our authoress very highly for much of sound common sense put forth with common honesty. It seems to us self-evident that "there is no virtue in bringing into the world a mass of puny, weak-minded, and vicious beings;" but then it requires a good deal of moral courage to say so at present.

SELECTIONS.

ARTIFICIAL RESPIRATION IN APOPLEXY.—In a recent number of the *Gazzetta d'Italia*, Dr. Corso, the assistant to the chair of Physiology at Florence, advocates the use of artificial respiration in cases of "fulminant" apoplexy, and of compression of the brain by hemorrhage or other causes. The immediate cause of his remarks was a case related in the same paper, in which a Dr. Despalles, of Brussels, employed the inhalation of oxygen in a case of apoplexy with hemiplegia with a successful result, the sensibility and power of movement returning in four hours. Dr. Corso claims that artificial respiration was first employed for apoplexy in Prof. Schiff's laboratory, and quotes the opinion expressed by Schiff in his lectures on the nervous system, published in 1866, that in cases of fulminant apoplexy produced by paralysis of the medulla oblongata, artificial respiration should be used, and never bloodletting. In 1871, Schiff also made numerous experiments on animals, and established the fact that the only way of preserving animals suffering from apoplexy, due to compression of the brain, from certain death, was artificial respiration. The explanation of this fact is that the immediate cause of death is paralysis of the respiratory centres by compression of the medulla oblongata, and the consequent non-oxygenation of the blood. The advantage of artificial respiration over the inhalation of oxygen is that it lowers the pressure of the blood in the intra-cranial vessels, and thus lessens the tendency to further hemorrhage.

In support of these views Dr. Corso relates a case in which he claims to have employed artificial respiration for the first time in such cases in the human subject. It was that of a lady who fell backwards and sustained a fracture of the skull. When seen, she was cyanotic, insensible, breathing slowly and superficially, the pulse also was infrequent and very feeble, and death seemed imminent. Artificial respiration was immediately performed, and continued for twenty minutes; under its influence the heart's action increased in force and frequency, the respiration became natural, and consciousness returned. The patient did not, however, completely recover, but died fifteen days afterwards from the laceration of the brain caused by the hemorrhage and fracture. Dr. Corso points out that had it not been for the irreparable lesions produced by the injury, the patient would have lived, and that the artificial respiration gives the brain and the medulla oblongata time to return to their normal functions, and hence a better chance of recovery, at any rate from the immediate danger.

There is no question that in many cases of coma due to compression of the brain, and also in that produced by opium or alcoholic poisoning, artificial respiration

might be used with advantage; perhaps also in cases of so-called "congestive" apoplexy; but it seems to us open to grave doubt whether it would be applicable to cases of severe cerebral hemorrhage. The fear of increasing the hemorrhage should make us hesitate to adopt it until clearer proof is given that the restored action of the heart would not increase the pressure in the cerebral arteries and destroy that quiescence in which seems to lie the only chance of recovery in many cases. The difficulty in diagnosing the exact cause of the apoplexy will also stand in the way of any general employment of this method, except where it affords the only chance of obviating immediate death.—*London Lancet*.

REPEATED SPONTANEOUS GANGRENE OF THIGH.—A widow 66 years of age had, following a pneumonia in April, 1870, a thrombus in the left popliteal artery. This caused gangrene of the limb, for which Prof. Estlander, on the 3d of May, amputated the leg at its upper third, finding the arteries atheromatous and the popliteal plugged by a thrombus, though the arteries of the leg were free. The treatment lasted till August, in consequence of gangrene of the flaps, and the patient was then discharged cured. She returned to the hospital October 6, 1873, having continued well till within two weeks, at which time gangrene recurred in the cicatrix of the stump and began to spread up the thigh. On examination the left thigh was found to be much thicker and fatter than the right; the slough extended on the outer side only about a hand's breadth above the knee, but on the inner side half-way up the thigh, without a distinct line of demarkation. On the 13th of October, as the extension of the gangrene had apparently ceased, amputation of the thigh was performed, during which it was noticed that the subcutaneous fat-tissue was solid and stiff, like that of a frozen cadaver, so that it was difficult to fold the flap. In the portion removed by the operation, the popliteal artery was found obliterated as far up as the tendon of the adductor magnus, corresponding to the extent of the thrombus discovered three years previous. With the exception of a slight tendency to gangrene in the skin of the flap, everything progressed well, and the patient was dismissed cured, February 19, 1874. Several days before leaving she said that everything she ate seemed to go into the stump, which again became much fatter than the remainder of her body.—*Finska läk. sällsk. handl. and Nord. Med. Arkiv.*, vol. vi. No. 3; *New York Medical Record*.

ABSOLUTE REPOSE IN TETANUS.—Prof. E. de Renzi draws the following conclusions from his observations of tetanus:

1. Light renders the tetanic contractions of animals and man more frequent and intense.
2. It can be demonstrated experimentally in animals, that absolute repose, during the absence of all stimulus, retards the tetanus and renders it less fatal.
3. Of three cases of severe tetanus, treated almost exclusively by absolute repose, two cases were cured. The patients were kept isolated in a dark room; all noise or other stimulus or irritation was avoided, except such as was caused by the administration of food and beverage at long intervals.
4. In one case death resulted, notwithstanding the administration of large doses of hydrate of chloral and several hypodermic injections of woorara. It would appear that the chloral increases the difficulty of respiration, which is already affected by the disease.
5. In the actual condition of science, absolute repose shows itself to be the principal remedy in the treatment of tetanus. The removal of stimulus should, however, be as complete as possible, and be recognized as an important accessory.
6. In two cases of traumatic tetanus, the first severe

tetanic manifestations occurred a few hours after the amputation of the injured limb. This shows that amputation, instead of impeding the further development of the disease, renders it more intense from the irritation of the nerves of the amputated part.—*Gaz. Med. Ital. Lomb.*, January, 1875; *New York Medical Record*.

GLEANINGS FROM OUR EXCHANGES.

THE OBSTETRIC FORCEPS AS A TIME-SAVER (*The Boston Medical and Surgical Journal*, July 1, 1875).—Dr. George E. Francis reports three hundred cases of labor which were completed within two hours after dilatation of the os, and in which the forceps were used fifty-one times, or once in six cases. There were three hundred and one children, all born alive but four.

Three of the mothers died; one of them was at the point of death when first seen, probably from pulmonary thrombosis, and the child being nearly born was safely extracted at the very moment its mother died. Another had erysipelas when labor set in, and died of blood-poisoning; the third was apparently exhausted by a very long first stage in which no interference was permitted; by the time the os was dilated she was in high fever. There have been no deaths in the one hundred and seventy-nine women last delivered. While it is true that the forceps was used in all three fatal cases, he sees no reason to think that the operation affected the results in either of them.

After delivery the perineum was always examined, and in but one case, which by the way was not instrumental, was there found sufficient tearing to need a stitch.

The application of the instrument rarely gave any more pain than the previous digital examination, and never required anaesthesia.

The catheter was not once required either during or after the confinement.

PENETRATING PISTOL-SHOT WOUND OF ABDOMEN—PASSAGE OF BULLET PER RECTUM ON FOURTH DAY—RECOVERY (*The Medical Record*, July 17, 1875).—Dr. William O'Meagher reports the case of an able-bodied man, who was shot in the umbilical region; the ball, from a No. 1 Smith & Wesson revolver, entering his abdomen. When first seen he was lying on his back in bed, complaining of pain, faintness, and chill, and restlessly moving from side to side. Without any unnecessary delay in vain efforts to find the bullet, the wound was cleansed, and closed by a compress of old linen, wet with cold water, covered with oiled silk, and kept in place by a broad bandage, tightly applied. During the examination and dressing he vomited freely about a quart of partly digested food and beer, in which, after careful examination, neither blood nor bullet could be detected. An opiate, combined with an alkaline diaphoretic, was freely administered, and ice, with carbonated water, allowed in small quantities to allay thirst. Directions were given to examine the excretions closely, and absolute rest on the back, with the knees in the flexed position, enjoined.

The next day he vomited a little, and on the day following had a chill, followed by symptoms of peritonitis. A bag of powdered ice was applied to the wound, and five grains of Dover's powder, with a grain of calomel, were administered every three hours. On the third day he was much better, and had an oleo-terebinthinate enema; and on the fourth day, having greatly improved, was given a castor-oil draught. This operated three times, and in the last passage the

bullet was found. His progress to complete recovery after this was uninterrupted by any untoward symptom. Dr. O'Meagher ascribes the favorable termination of the case to the smallness of the missile; to the early closure of the wound; to the entire absence of attempts to find the bullet by probing, a species of surgery not only meddlesome, but criminally dangerous; to abstinence from food and drink except in small quantities; to absolute rest, and a good constitution.

CHRONIC CYSTITIS OF MANY YEARS' STANDING CURED BY THREE INJECTIONS OF A STRONG SOLUTION OF NITRATE OF SILVER (*New Orleans Medical and Surgical Journal*, May, 1875).—At the clinic of the Charity Hospital, Prof. Richardson lectured upon a case of chronic cystitis in a man *æt.* 44. He commented particularly upon the great caution advised by most authors in the use of even a very weak solution of nitrate of silver as an injection. He stated that for several years past he had invariably employed in such cases solutions varying in strength from ten to sixty grains to the ounce of water, and with almost uniformly successful results. He argued that an injection of less than ten grains is utterly worthless, in consequence of its immediate decomposition by the small quantity of urine which it is sure to meet with as soon as it enters the bladder.

He then proceeded to wash out the patient's bladder with tepid water, and followed the discharge of the latter immediately with two ounces of a solution of nitrate of silver, twenty grains to the ounce. This latter was allowed to remain in the organ about a minute, and then to flow out through the catheter, the salt having in the mean time become almost entirely precipitated in the form of chloride of silver. The injection was not succeeded by another of tepid water for washing out the remains of the nitrate of silver. This is not necessary except where much stronger solutions are employed. The patient complained for a few hours of a severe burning at the neck of the bladder; but the next morning he expressed himself as feeling remarkably well. In fifty-eight hours there was a marked improvement in the character of the urine, and great amelioration of the dysuria, which had formerly been very annoying.

After the lapse of eight days another injection was made, containing thirty grains of the salt to the ounce of water. This was followed by a corresponding improvement. Again, in eight more days, the same was repeated, after which every particle of pus and mucus disappeared from the urine, together with all other symptoms of inflammation. Owing to the permanently contracted state of the bladder, the patient is unable to hold his water longer than three or four hours; but even this may be improved by daily repeated efforts, with a view to put the bladder slightly upon the stretch, and thus gradually increase its capacity.

SYPHILITIC SARCOCELE (*The Medical Press and Circular*, June 30, 1875).—Dr. Thiry remarks that a peculiarity worth noting in cases of slow evolution of syphilis is that it is the glandular organs, and especially the testes, that are affected. Syphilis concentrates itself for a long time in the testicle, and only attacks the other tissues later on. In this case the syphilis is not less grave; the more time it has required for its development the longer it will require to disappear. A long and persistent treatment will be required. He prescribed four pills of five milligrammes of corrosive sublimate a day, one to be taken in the morning, one at noon, one at 4 p.m., and one in the evening in a glass of decoction of sarsaparilla. Mercurial friction of a quarter of an hour to be made on the internal aspect of the legs, thighs, and arms. After each two frictions a bath of starch to be taken. The diet strictly confined

to roast meat and vegetables, and the patient to abstain from acids.

As a general rule, we have found large doses of the iodide of potassium to effect such a rapid cure in similar cases that we are a little surprised to find that Dr. Thiry has not made any use of this medicine in this case. Doses of one gramme, or fifteen grains, thrice or four times daily, in plenty of water, act marvellously well.

THE TREATMENT OF STRANGULATED HERNIA BY THE USE OF A DILATOR (*The Medical and Surgical Reporter*, July 10, 1875).—Dr. H. R. Allen, of San Francisco, describes an instrument devised by himself for dilating or rupturing the stricture which exists in cases of strangulated hernia. The amount of laceration produced by it is very slight, and is entirely under the control of the operator, but is sufficient to relieve the strangulation of blood-vessels and permit the congestion and tumefaction to disappear, and usually allows the return of the hernia in a few hours. At the same time it has proved an advantage by causing sufficient inflammation of the ring to produce adhesion, if a firm truss is at once employed, and quiet enjoined. The distention employed carries the parts in the stricture upward, and away from the hernia, and not a particle of pressure is exerted upon the constricted tissues: hence no wounding of those parts occurs.

One great advantage is, that it is admissible at any stage when the parts are not fatally injured, and, if employed immediately when taxis fails, all danger of inflammation or gangrene is avoided.

ELECTRO-PUNCTURE IN HYDROCELE.—Dr. Ehrhardt (*Boston Medical and Surgical Journal*, July 15, 1875) has tried radical treatment of hydrocele by electro-puncture four times with permanent success, using the interrupted current of the small apparatus of Gaiff. In three cases the hydrocele had existed only a short time, and tapping had not been resorted to; the fluid, although in considerable quantity, was absorbed in three to five days without any reaction. In the fourth case the fluid was absorbed by the end of three weeks. In this case the patient was fifty-two years old, with a hydrocele on the right side, of eight years' standing; he had had it tapped often. After tapping, the fluid had returned at the end of three weeks. The operation was performed in the following manner: Two large, sharp-pointed, inverted needles, connected with the pole of the apparatus, were thrust into the swelling at a distance of six centimetres from each other, and to a depth of three centimetres, so that the needle projected into the fluid. The tunica vaginalis was very tough and thickened, so that there was some difficulty in inserting the needles. There was but little pain, the application lasting about five minutes. The needle of the negative pole on being withdrawn appeared blackened and oxidized. The patient, as a matter of precaution, remained two days in bed. Four months later there was still no return of the fluid. The author thinks that this method could not probably be effective where there was considerable alteration in the tunica vaginalis.

MISCELLANY.

LONGEVITY IN ENGLAND.—The mortality returns for England for the year 1872 show that 195 men and 433 women died at 95 years old and upwards. Of this number 24 men reached or exceeded 100 years, one attaining 111 years. Of the women, 51 reached or exceeded 100 years, two having died at the age of 107. Of the whole number remaining, men and women, two

died at 101, two at 102, one at 103, two at 104, and one at 105.—*New York Medical Record*.

SOLUBILITY OF GLASS.—Glass vessels in which various liquids, and even pure water, are boiled, give up by degrees a small quantity of their substance,—silica, potash, soda, and lime. The analysis is the more misleading the longer the boiling is continued. This, at least, was what resulted from German glasses sold at Nancy in 1874. The fact may be shown by boiling in a flask pure water, mixed with a tincture of red cabbage, or syrup of violets slightly reddened by an acid. After a few minutes the liquid turns green. French glasses, with a base of soda, are not sensibly attacked, and therefore do not suffer this inconvenience.—*Pharmaceutical Gazette*.

FROM the annual report of the receipts and expenditures of the Royal College of Surgeons of England, which was submitted to the Council on the 8th ult., it appears that the former amounted to £16,057 12s. 4d., and the latter to £14,052 8s. 2d., showing the good balance of £2005 4s. 2d. The income is derived principally from fees paid on examinations for the diplomas of fellow and member and of dental and obstetric licentiate, which produced £11,156 7s.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

PHILADELPHIA, PA., August 3, 1875.

DEAR SIR,—In my communication on "Nitrite of Amyl in Hysterical Convulsions," etc., published in your journal of July 31, *Case I.* reads, "a series of *subintense* convulsions," which is a typographical error; it should read, "a series of *subintrans* convulsions." The word *subintrans*, used by Trousseau in his clinical lecture on "Convulsions," means that as the patient passes out of a convulsion he immediately passes into another convulsion, or that before the convulsion subsides another comes on.

Yours truly,

RUFUS K. HINTON, M.D.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM AUGUST 3, 1875, TO AUGUST 9, 1875, INCLUSIVE.

MIDDLETON, J. V. D., ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 83, Military Division of the Missouri, Aug. 2, 1875.

HUNTINGTON, D. L., ASSISTANT-SURGEON.—Relieved from duty in Department of California, and to report in person to the Surgeon-General. S. O. 158, A. G. O., Aug. 5, 1875.

BROWN, HARVEY E., ASSISTANT-SURGEON.—Assigned to duty at Fort Barrancas, Florida. S. O. 141, Department of the Gulf, July 31, 1875.

KIMBALL, J. P., ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 147, Department of Dakota, Aug. 3, 1875.

STYER, CHARLES, ASSISTANT-SURGEON.—Assigned to duty at Fort Macon, N.C. S. O. 109, Department of the South, Aug. 3, 1875.

MAUS, L. M., ASSISTANT-SURGEON.—Assigned to duty at Nashville, Tennessee. S. O. 111, Department of the South, Aug. 6, 1875.

KILBOURNE, H. S., ASSISTANT-SURGEON.—Assigned to duty at Fort Gibson, Indian Territory. S. O. 139, Department of the Missouri, Aug. 3, 1875.

BARNETT, R., ASSISTANT-SURGEON.—Assigned to duty at Coushatta, La. S. O. 145, Department of the Gulf, Aug. 5, 1875.

CRAMPTON, L. W., ASSISTANT-SURGEON.—Assigned to duty with Battalion 13th Infantry, in camp at Mississippi City, Miss. S. O. 142, Department of the Gulf, Aug. 2, 1875.

WOOD, M. W., ASSISTANT-SURGEON.—Assigned to duty at Camp Douglas, Montana Territory. S. O. 87, Department of the Platte, Aug. 4, 1875.

LORD, G. E., ASSISTANT-SURGEON.—Assigned to duty at Fort Buford, Dakota Territory. S. O. 145, Department of Dakota, July 31, 1875.

SATURDAY, AUGUST 21, 1875.

ORIGINAL COMMUNICATIONS.

PARACENTESIS THORACIS.

A Lecture before the Oxford, Pa., Medical Society,

BY JAMES TYSON, M.D.,

Professor of Pathological Anatomy and Histology in the University of Pennsylvania; one of the Physicians to the Philadelphia Hospital, etc.

PARACENTESIS of the chest is by no means a new operation, and I cannot, therefore, base the propriety of my detaining you with its consideration on any such assumption. It is not, however, so frequent an operation as it should be, and on this ground I may be justified in pointing out some of the indications for its more frequent performance, the simplicity of the operation itself, some of the instruments which have rendered the operation so easy and harmless, and, finally, one or two instances of the happy results derived from its use.

The object of the operation, as is well known, is to evacuate fluid, serous or purulent, from the chest by perforating the chest-wall, now invariably in an intercostal space, but formerly, also, by boring through a rib. It is, as stated, by no means a new operation, but was performed as far back as the era of Hippocrates, for the same objects as it is performed to-day, and with surprisingly little difference in the essentials of procedure. But, although it continued to be done from that remote era to the present, having, like transfusion, a varying popularity, we are indebted to the great French clinician Trousseau for establishing the operation on a sound basis. To his admirable work on clinical medicine I must also refer you for the details of its history, which is full of interest. Trousseau's first memoir on the subject, containing a report of three cases, was read to the Academy of Medicine in 1843. Two principles, at one time disputed, had, up to this date, been determined: first, that the fluid might be drawn rapidly from the chest without harm,—that is, all at one sitting, instead of a small quantity on successive days; and, secondly, that while it was desirable, as much as possible, to prevent the entrance of air into the chest, this was by no means absolutely necessary, as the chances of consequent injury were trifling. During this period, also, the trocar had come to be substituted for the bistoury; the trephining of the ribs had been omitted, and a variety of means had been suggested for plugging temporarily the external orifice of the canula.

I believe Trousseau has correctly assigned the reason for the unsettled position which paracentesis thoracis had attained among operations up to his own period. This cause* he states to arise from an "insufficient knowledge of the indications for operating, and not from any imperfection in the mode of performing the operation." He goes on to say, "It is impossible for any therapeutical means to be regarded with general favor, be it a medicine or sur-

gical operation, unless it be suited to a determined exigency. A remedy will remain unemployed so long as the circumstances which demand its employment are unknown. Or at most, an experimentalist tries it at a time, in a sort of hap-hazard way, and announces a successful result; others who attempt to follow in the same direction either use the remedy too timidly or too indiscriminately, thus discrediting it and causing it to fall into oblivion. Such has been the fate of paracentesis of the chest."

Up to the beginning of the nineteenth century, the only evidences of fluid in the chest were the sounds produced by *succussion*, and the bulging of the intercostal spaces, although it was said by Murinna, a German surgeon, in 1811, that a *dull* sound of a very peculiar character was sometimes heard on percussion. The same author, besides insisting upon the phenomena of succussion as absolutely essential to diagnosis, also said that œdema of the inferior extremities and of the scrotum was almost invariably present.

With the discovery of auscultation and the elaboration of its results and those of percussion by Laennec and his followers, the vagueness of information as to the presence of the condition requiring paracentesis of the chest passed away. But the distrustful, uncertain attitude of this very discoverer towards the operation was largely influential in preventing it from being properly appreciated until Trousseau established it upon a firmer basis after the year 1843, although in Germany it was more popular. In England it was discouraged by such authorities as Hope, Stokes, and Watson.

Since this period, in addition to Trousseau in France, Bowditch in America, Stokes of Dublin, and Budd of London have done most to popularize the operation. Conspicuous among these is Dr. Bowditch, of Boston, who up to 1868 had performed the operation one hundred and fifty times on seventy-five persons: *eight* times in six weeks on the same patient, a physician, and *nine* times in eight and a half months on a lady,—beginning when she was pregnant four and a half months, when dyspnoea was threatening death,—and who was delivered at full term, and completely recovered; Dr. Bowditch has consequently come to be regarded as the most eminent American authority on the subject.

But, notwithstanding these results and the comparative frequency of the operation, paracentesis is still too infrequently performed, and I am confident that, if the lives of many are not sacrificed, patients are, at least, unnecessarily made to suffer weeks and even months longer than they should through omission of the operation. Such an omission at the present day can be attributable only to one of *two* causes: 1, an unnecessary timidity, or apprehension that the operation is a serious one; and, 2, a feeling of indifference, based upon an idea that a patient is rarely if ever killed by a thoracic effusion, and that in the course of time the effusion will disappear through the agency of diuretics, or even without any treatment directed especially to the effusion.

That the timidity referred to is not altogether

* Sydenham Society's Translation, vol. iii. p. 208.

without foundation might be inferred from the fact that Laennec himself once transfixed the diaphragm and pierced the liver, and that through the *fifth* intercostal space; while Dr. Watson, of London, once witnessed an operation in which the trocar was pushed through the diaphragm into the spleen, which was unusually large, the patient dying of peritonitis a day or two afterwards. At the same time, I think I can show you that such accidents as these can be avoided, especially with this knowledge that they have occurred previously.

With regard to the second cause of infrequency of the operation, it is erroneous and inexcusable from either point of view; for, in the first place, death from the effects of pleuritic effusion is by no means a rare occurrence,—some striking examples are given by Trousseau,—and, in the second, apart from the risks of tuberculosis and empyema, which are well known to exist during a long-continued pleuritic effusion, we have no right to keep invalid and unemployed for many months a patient whose time and labor may be a means of support to others, to say nothing of his personal discomfort.

And this suggests the circumstances under which the operation may be called for. What are they? These are the chief. First, where in consequence of extreme accumulation of fluid in the chest, whether rapid or slow, there is danger of death from syncope, heart-clot, or asphyxia; the first two from impediments to the circulation, the second from encroachment upon the breathing-space and resulting deficient aeration. These are indicated by extreme weakness, disposition to fainting, great dyspnoea, often amounting to orthopnoea, lividity of the face, and other symptoms of embarrassed breathing, as well as displacement of the heart and the physical signs of effusion. Second, in those extreme or more moderate accumulations of *latent* pleurisy in which, although the above dangers may not be markedly present, the recovery of the patient is likely to be materially retarded by their presence. Among the most common evils which are apt to ensue upon the long-continued presence of a serous chest-effusion is an *empyema*. Almost never is a purulent product the primary result of a pleurisy, except in certain conditions of the system induced by the puerperal state, and the eruptive fevers, especially smallpox and scarlatina, although in children the serous effusion is apt to become purulent at a much earlier date; and in all cases, the longer an effusion lies in a chest the more likely is it to become an *empyema* with its destructive hectic. Such a grave substitution as this we can best prevent by paracentesis, while the presence of an empyema, whether primary or secondary, gives us the third indication for operation. Not that the otherwise invariably fatal termination of an empyema is averted, for the opposite result of the case I show you to-day is an exceptional one; but it at least retards the fatal end, saves the lives of some, and in children a favorable issue is not uncommon. Fourth, with the light modern pathology has shed upon the causation of tuberculosis, long-continued pleuritic effusion being one of the best-established causes, we have in this fact another, which should prompt to a

tapping of the chest when serous or purulent fluid is present. Fifth, in the pleuritic effusions which so constantly ensue in the course of valvular disease of the heart and Bright's disease of the kidney, paracentesis may be performed for the relief of dyspnoea discomfort, and to relieve the blood-vessels from that pressure which impedes absorption and prevents the removal of dropsies in other parts of the body.

Finally, paracentesis may even be performed for the great relief of the patient where pneumothorax co-exists with effusion, where the pleura has been perforated by ulceration in phthisis, or even, according to Trousseau, in cancer of the pleura. These are, of course, the most unfavorable cases, and only temporary palliation may be expected from them.

We have next to consider the *site* and *method* of performing the operation. Apart from the fact that circumstances must sometimes modify the selection of the point of puncture, there has been by no means a unanimity of opinion. Other things being equal, sufficient distance from a vital organ, a point which will secure the best drainage, and thinness of the chest-walls are the guides to success.

Trousseau selects the sixth or seventh interspace, nearly four or five centimetres (one and three-fifths to two inches) external to the outer edge of the pectoralis major muscle.

Dr. Bowditch chooses an interspace about an inch and a half above the lowest level at which the respiratory murmur can be heard on the opposite or healthy side. I have myself always, as nearly as possible, taken a point named by Dr. Aitken, between the seventh and eighth, eighth and ninth, or ninth and tenth ribs,—most frequently, perhaps, between the eighth and ninth,—in a line let fall from the inferior angle of the scapula, as giving all the advantages of dependence, thinness of chest-walls, and remoteness from liver or spleen. In all instances, however, the vicinity should be explored by auscultation and percussion, with a view to detecting deviations in the situation and size of these organs. With such precautions I think it almost impossible to make the mistakes already referred to as having been made by Laennec and others.

The patient, if not too feeble, may sit astride a chair, steadying himself by seizing the back, or, if feeble, he may be brought to the edge of the bed, resting in the arms of a friend.

Trousseau insists very strongly upon the skin, at the point to be perforated, being first incised by a lancet or bistoury; but I have never done it, seeing no necessity or even advantage in such a course. Others, again, seek to benumb the sensibility by holding a piece of ice to the part; but I do not think sensibility is practically diminished by such a course. Complete local anæsthesia may, of course, be obtained by throwing the rapidly-evaporating rhigoline against the part by an atomizer; but the advantage derived is more than offset by the alarm which must grow out of so much parade of apparatus and time occupied in preliminaries. I therefore at once perforate, without attempting to induce local anæsthesia. Much of the apprehension which

formerly existed with regard to the access of air to the pleura, and a resulting conversion of a simple serosity into an empyema, is unfounded, so that it is really not necessary to have an air-tight apparatus; at any rate, the operation should not be deferred for the want of one, but an ordinary moderate-sized trocar, such as I show you, and which I have several times used, will answer very well. The point selected, the end of the index-finger is pushed well into the interspace, and the trocar, inclined upwards so as to be turned away from the liver or spleen, is thrust in between the finger and the upper border of the inferior rib. The lower border of the upper rib is avoided, so as to escape the intercostal artery; although there is little danger of wounding it,—Trousseau says it has never happened,—because the vessel is contained in a groove on the inner and under surface of the rib. The operator perceives in a moment when he is within the chest-cavity, in consequence of the diminished resistance, just as we know we are within the bladder in introducing a catheter. The trocar is then withdrawn, and most generally the fluid begins promptly to flow through the canula. Two causes may, however, interfere with immediate success. The most frequent of these occurs where a false membrane of so recent formation exists that it is but slightly adherent to the chest-wall, and consequently is pushed off when the trocar has passed through the muscles. This is more likely to occur when the trocar is timidly or slowly passed than if it is quickly plunged. Should this occur, the membrane may be generally broken or torn by passing a probe through the canula and moving it about. Sometimes, it is said, it may be necessary to withdraw the canula and perforate in another spot; but I have never met the accident, even in its less serious degree.

Another cause of deficient flow is occasionally found in a circumscribed or sacculated pleurisy, where, in consequence of partitions of false membrane, the pleural cavity is divided into more or less perfect compartments, which usually, however, communicate with one another. These may drain slowly, and finally the flow may cease altogether before the chest-cavity is empty. It is recommended to attempt to break up these partitions by suitable blunt-pointed instruments or probes.

Another cause of delayed flow mentioned by Trousseau is an indisposition on the part of the patient to use the corresponding lung in breathing, either from habit or a nervous condition. This effect is combated by asking the patient to cough or to strain as at stool; but the former request soon becomes unnecessary, as an irresistible disposition to cough very soon presents itself, and often becomes very annoying, continuing long after the operation is completed. It is, no doubt, due to the irritating influence of the inspired air, to which the compressed lung has long been unaccustomed. Extreme pain is also sometimes experienced from the same cause. Both may be controlled by the use of an opiate immediately after the operation,—a hypodermic injection of morphia affording the most convenient and reliable mode of exhibition.

But although an ordinary trocar and canula are sufficient for the operation of paracentesis, yet, in view of the greater facilities afforded by special instruments for thoroughly emptying the chest, as well as the fact that there is some risk of converting a serosity into a purulent fluid by the access of air, it is well to use some form of the so-called aspirators now used for this purpose, and for emptying other cavities where it is desirable to prevent the access of air or to avoid extensive incision. Trousseau always operated with a trocar and canula, to which a piece of gold-beater's skin or similar substance was attached, so that when wet it fell over the opening of the canula, and, acting like a valve, allowed the fluid to flow out, but prevented the air from entering.

The best of the early modern instruments devised for this purpose was the so-called Bowditch's apparatus, originally made for him by Codman & Shortleff, of Boston. It consists of a moderate-sized trocar, with a canula capable of being attached by an intermediate tube to a syringe provided with a stop-cock so arranged that when open it permits the suction of fluid from the chest, while a second opening communicating with the exterior is closed. When the syringe is filled, the opening communicating with the chest is closed, and on pushing in the piston the fluid is forced out through a second tube, the end of which may be submerged, if desired, in a vessel of water provided for this purpose. Then this opening is closed, and the syringe again filled from the chest, and emptied as is shown. The apparatus is a good one of its kind, and, except that the barrel of the syringe is metallic and therefore not transparent, it appears to me as good as the more recent apparatus of Dieulafoy next shown, and now well known as the aspirator. It was devised, as is well known, for draining fluids without access of air, by fine perforated canulæ, from any deep-seated situation, as a renal abscess or the bladder. The principle is identical with that of Bowditch's apparatus, but the fine canulæ are commonly used, and the barrel of the syringe, being of glass, permits the fluid to be examined through it.

It is a matter of extreme difficulty, however, to get a glass cylinder which is perfect, and much care must be exercised in selecting an instrument. Further, both of the above instruments are very apt to get out of order, and it is almost indispensable, in order to be sure of their successful operation, to have them overhauled by the instrument-maker immediately before using. Finally, the muscular effort required in their use is considerable, and if the quantity of fluid to be evacuated is large, considerable fatigue ensues.

Neither of these objections can be made to the next instrument I show you,—the aspirator of Potain, and made by Gemrig of this city,—which is by far the best yet introduced. The perforating apparatus is similar, but the exhausting apparatus consists of a bottle,—any wine- or beer-bottle will answer,—which receives a rubber stopper communicating on the one side with the fluid-cavity, and on the other with an air-pump syringe, from either of which it is capable of being cut off by a stop-cock.

When the bottle is exhausted by the air-pump, the proper attachments are made, and the chest perforated; the communication with the chest is then opened, and the fluid flows rapidly into the bottle, even through the needle or exploring canula,—so

rapidly, indeed, that I have never had occasion to substitute a larger canula for this exploring one. When the vacuum seems nearly filled, the air-pump is again brought into requisition, and when full the bottle is emptied, the communication with the chest being cut off by the proper stop-cock; after which the attachment is again made, the bottle emptied of air, and the fluid allowed to run until the receiver is full. As a receiver of large capacity may thus be used, it is evident that the effort required to empty a chest of many ounces is comparatively trifling.

A very convenient apparatus for simple exploratory purposes is the ordinary glass barrelled hypodermic syringe, by which a small quantity of fluid may be drawn from the chest and examined without danger of entrance of air.

(To be continued.)

RUPTURE OF EXTERNAL ILIAC ARTERY— DEATH ON TWELFTH DAY FROM IN- TERNAL HEMORRHAGE.

Read before the Pathological Society of Philadelphia, June 24, 1875,

BY JOHN ASHHURST, JR., M.D.,

Surgeon to the Episcopal Hospital, etc.

A. R., an engineer, 39 years of age, and a native of this country, applied for admission to the Episcopal Hospital on June 15, 1875, saying that one week before he had, in trying to board a railway-train, slipped and fallen backwards, striking a rail of the adjoining track, and receiving a severe blow in the region of the lumbar spine. But slight inconvenience from the injury was experienced at the time, but the next morning the patient felt stiff, and had a good deal of pain in his back,—these symptoms becoming more, rather than less, marked

during the following days, though even when admitted to the hospital he walked without difficulty, and considered himself, and was considered, to be suffering merely from a contusion or sprain of the lumbar muscles.

This was on Tuesday. On the following day the patient was in much the same condition, and gave no evidence of having received any serious injury. His bowels were moved by a mild laxative.

On Thursday, June 17, I found the patient in a cold sweat, and then learned that a similar "sinking spell" had occurred on the preceding day, but had passed off in a short time, and had been, apparently, of a trivial character. The patient now complained of pain in the left side as well as in the back, but there was no great tenderness manifested on palpation, and nothing was discovered to throw any further light on the case. The left common femoral artery was observed to be pulsating with great force, but the pulsation was not expansile in character, and a slight fulness which existed below Poupart's ligament was evidently due to an enlargement of several lymphatic glands. There was no abnormal pulsation nor tumor in the course of the iliac artery.

On Friday, June 18, the patient was almost in a state of collapse, bathed in a profuse cold sweat, with rapid respiration, and with a pulse running at the rate of 120 or more beats in the minute; he had more pain, still referred to the back and left flank (rather in the hypochondriac than in the iliac region), and vomited a little after taking food, though his diet was limited to milk, mixed with lime-water, and a moderate amount of stimulus. There was no tympanites and no general abdominal tenderness, and the tongue was, as it had been throughout, moist and clean. The pulsation in the common femoral artery was now rather feeble; but there was, on the other hand, a marked pulsation in the epigastric region, perceptible both to sight and to touch; auscultation, moreover, revealed a bruit, not, however, of a very decided character, and not propagated for any great distance along the course of the aorta. There was no bruit in the iliac region. Careful palpation failed to discover a tumor in any part of the abdomen, though there was a slight fulness in the left flank, such as is sometimes observed at an early stage of psoas abscess.

As elucidated by the results of the post-mortem examination, the signification of the various symptoms now seems plain enough; but at the time I confess that I felt some hesitation in making up my mind as to the precise nature of the injury. Three conditions presented themselves to my consideration as possibly present,—viz., internal strangulation, latent peritonitis, and internal hemorrhage. The supposition that strangulation existed was negatived by the state of the patient's tongue, and by the absence of constipation; the same circumstances, together with the total absence of febrile excitement, contradicted the notion of peritonitis; and by a process of exclusion, therefore, I was led to think that the symptoms observed were due to internal bleeding. The source of the hemorrhage was next to be considered. The constant pain in the left

flank suggested the existence of rupture of either the spleen or the left kidney; but a careful examination of the patient's urine, made by my very competent house-surgeon, Dr. Rudderow, failed to detect the presence of either blood or albumen, and I could hardly believe that a splenic rupture, of sufficient gravity to prove fatal, could have existed more than a week without giving evidence of its presence. I had, indeed, seen lacerations of the spleen which produced no symptoms during life, and which were only discovered after the death of the patient from other causes; but a rupture so extensive as to endanger life by hemorrhage would certainly have proved fatal at an earlier period. Here, again, then, by a process of exclusion, I was led to believe that the patient was bleeding from a large artery, which had undergone partial rupture at the time of the original injury, and that the efforts of nature to repair the lesion, though temporarily successful, had ultimately allowed the occurrence of profuse hemorrhage. Thus far my opinion was proved correct by the results of the autopsy, but I was misled—and, I think, naturally misled—by the absence of pulsation or bruit in the iliac region, and by the presence of both in the epigastrium, to infer that the injured vessel was either the aorta itself, or one of its large abdominal branches.

On Saturday, June 19, I found the patient almost moribund. There was now a good deal of tympanites, but no general abdominal tenderness; the patient's tongue was still clean and moist; vomiting had ceased, and the administration of a simple enema had produced three copious fecal evacuations. That which the day before was only a fullness in the left flank, now appeared to form an elongated tumor; but the tension of the abdominal muscles on this side was so great that in the patient's prostrated condition no accurate examination was possible. The left-sided pain and tenderness were still increased, and to my former diagnosis of internal hemorrhage I now added that of localized peritonitis. The patient died a few hours after my last visit.

A post-mortem examination was made the next day by Dr. T. H. Andrews, one of the coroner's physicians. On laying open the abdomen, recent peritoneal adhesions were found upon the left side, and beneath the peritoneum was found an enormous clot filling the left vertebral gutter from the pelvis to the diaphragm, and above turning inwards and compressing the aorta. The clot having been removed, the source of bleeding was found in a rupture of the left external iliac artery, about half an inch below the bifurcation of the common trunk; both ends of the torn vessel were retracted, though held together by a portion of the external coat of the artery, and the distal end was partially occupied by a well-formed coagulum. The abdominal viscera, as far as examined, presented a normal appearance.

The symptoms presented in this case were now readily explained. An incomplete rupture of the external iliac artery no doubt occurred at the time of the patient's injury, but either the external coat of the vessel remained intact, or, if it was involved

in the rupture, a clot was formed, and the bleeding was temporarily arrested. Hemorrhage began or recurred on the eighth or ninth day, and on account of the anatomical relations of the vessel, bound

A, common iliac artery; B, external do.; C, internal do.; D, position of rupture; E, clot overlying common trunk; F, clot protruding from distal end of external iliac artery.

down as it was by the iliac fascia, the blood found its way upwards, dissecting up the peritoneum, and finally impinging upon the aorta, thus by pressure producing the pulsation and bruit which misled me as to the situation of the lesion. The femoral pulsation noted on June 17 showed that at that time blood was passing freely through the injured vessel, and was no doubt the forcible pulsation often observed in the arteries of a part from which secondary hemorrhage has occurred or is about to occur. As the bleeding went on, the clot formed about the injured artery exercised a certain amount of compression, and the violence of the pulsation was diminished. With the consequent enlargement of the coagulum, the peritoneum was more and more separated from its attachments, giving rise to steadily increasing pain, and ultimately leading to localized peritoneal inflammation. The arterial rupture was too extensive to permit the formation of a traumatic aneurism, and when secondary hemorrhage occurred the patient literally bled to death.

I have said nothing as to the treatment adopted in the above case, for, in the absence of any certain knowledge as to the nature of the injury, it was, of necessity, purely empirical, and directed to the relief of symptoms; and though it may have prolonged life for a few hours, it of course exercised no influence for either good or evil, as regards the ultimate termination of the case. Had it been possible during life to determine the exact source of bleeding, the propriety of attempting the application of ligatures to the injured vessel would have had to be considered.

NOTES OF HOSPITAL PRACTICE.

ST. BARTHOLOMEW'S HOSPITAL, LONDON.

SERVICE OF MR. CALLENDER.

Reported by JOHN B. ROBERTS, M.D.

OPERATION FOR THE RELIEF OF STRANGULATED FEMORAL HERNIA.

AN elderly woman was admitted, who had had a hernia for many years, and who said that it had always been possible to push the bowel back. On closer examination, however, it was evident that she had never been able to replace it entirely, and that a portion of the protruded abdominal contents always remained external to the opening in the parietes, constituting, therefore, an incompletely reducible hernia. Three days before her admission the tumor became larger, and thus attracted the patient's attention; it could not be pushed back as usual, and soon became somewhat painful, though not especially so.

On examination, quite a large tumor was seen at the upper part of the thigh and in the right groin, extending from the external femoral ring upwards and outwards over Poupart's ligament, but its position was such as to render the diagnosis between femoral and inguinal hernia easy, since it did not extend towards the labium. The superior spinous process of the ilium, which was readily found, although the patient was fat, gave the direction of Poupart's ligament, and thus afforded a guide to the character of the hernia; the pushing upwards of the tumor being probably due to the mass of veins emptying into the saphena and femoral veins at this point. There was little or no resonance on percussion, the tumor did not have an impulse when the woman coughed, and she had neither vomited nor even felt nauseated; but the tumor felt tender, her bowels had not been opened for several days, and her tongue was coated quite heavily. Taxis had been attempted by a surgeon outside, who, being unsuccessful, had advised her removal to the hospital.

Although the symptoms were not very urgent, an operation was indicated, because it was evident that the strangulation, if not relieved, would lead to mortification, and therefore, as the life of the patient was jeopardized, it was deemed proper to use the knife. The woman was etherized, and a last attempt at taxis made under the relaxing influence of the anæsthetic; but, this proving unsuccessful, the operation was begun. A vertical incision, two and a half inches long, was made over the most prominent portion of the tumor, cutting from without inward, and not by transfixing, as is sometimes done. When the sac was reached, an endeavor was made to replace the mass, sac included, into the cavity of the abdomen; but the many adhesions rendered this impossible, and therefore the bands of fibrous tissue were torn by the finger, or, when they were very firm, divided with the knife.

As it was impossible to force the mass back through the opening in the abdominal parietes, the sac formed of the parietal peritoneum was slit open on a director, whereupon a small amount of serum escaped. It then became evident that the hernia was an epiplocele, for there could not be found a single coil of intestine protruding; whence the negative character of the symptoms presented by the patient when first examined. The constriction exerted by Gimbernat's ligament was relieved by introducing a narrow knife into the wound and cutting the edge of the ligament, after which procedure the protruded omentum was replaced without difficulty. This is a very delicate step in the operation, on account of the occasional abnormal distribution of

the arteries, which must, therefore, be remembered in all cases.

A tent was introduced into the wound, to facilitate drainage, the carbolized oil dressing was applied, without any sutures being used, and the administration of an opiate was ordered.

[One week subsequent to the operation the patient was doing well, and everything seemed to point towards a favorable issue of the case.]

ST. THOMAS'S HOSPITAL.

SERVICE OF MR. SYDNEY JONES.

SUBCUTANEOUS DIVISION OF THE NECK OF THE FEMUR IN A CASE OF BONY ANCHYLOSIS OF THE HIP-JOINT.

THIS man presents a remarkable deformity, resulting from an attack of what was called rheumatic fever, though more likely pyæmia, from which he suffered about six years ago. When he was admitted to the wards there was anchylosis of both hips and also of both knees, so that he could only take exercise by using two crutches. The anchylosis of the knee-joints has been overcome by breaking up the adhesions by powerful passive motion, but it was found impossible to rupture the osseous union between the head of the femur and the ilium on either side; so that it has been determined to attempt, on the right side, the formation of a false joint by sawing through the neck of the thigh-bone. The femurs are abducted and rotated outwards, so that when the patient stands his feet are widely separated, and he assumes a semi-stooping posture. This terrible deformity is a warning to the surgeon to take the precaution to keep the limbs in a proper position in every case where there is danger of anchylosis occurring.

The operation of division of the neck of the femur for treating bony anchylosis of the hip was first done here by Mr. Adams, and, as in the present instance there is not the least movement possible, it seems a proper case for the employment of this operative interference. The operation will probably be an easy one, since there has most likely been no destruction of the head or neck of the femur, and the anatomical relation of the parts has, therefore, been preserved: it may, however, be necessary to divide also the tensor vaginæ and rectus femoris muscles, which during the long period may have assumed a condition of spastic contraction.

The outline of the femur is first sketched on the skin in ink, and then a small puncture is made, and a tenotomy-knife introduced half an inch above and a little in front of the great trochanter, thus clearing the anterior surface of the neck. The soft tissues are divided thoroughly with the knife, which, as it is withdrawn, is made to enlarge slightly the cutaneous orifice, in order to allow free play for the saw, and thus prevent the occurrence of a ragged wound externally. The next step is to introduce along the track of the knife a narrow saw, which is passed flatwise, and then turned with its cutting edge against the bone with great care, lest the instrument snap and a fragment be left in the wound. The saw is now in position, and its extremity felt in the tissues by the left hand of the surgeon placed upon the upper part of the thigh; it is carefully moved back and forth until the neck of the femur is sawn entirely through, when it is withdrawn, and the thigh forcibly twisted into a much better position. As the bone was being sawn, the end of the instrument was felt to impinge against some hard substance, which was most probably the lesser trochanter.

The flow of blood, though quite considerable, is not at all abundant; but a pad shall be placed over the femoral artery just below Poupart's ligament, and con-

fined by adhesive strips, in order to cut off the supply to the smaller vessels that have been wounded. After a piece of oiled lint has been placed upon the wound, the entire limb is surrounded by a bandage.

The ankylosis having existed for six years, the muscles have accommodated themselves to the deformity, and will, therefore, tend to draw the femur into its old position: hence it is necessary to apply a splint along the outside of the leg, from the ankle upwards, to retain the limb in its present improved position. The splint is composed of two sections,—one long piece extending from the foot to a point just below the hip, and a second from above the joint along the trunk: these sections are connected by a curved rod of iron, for the object of the splint is, since we are aiming at the production of the false joint, not to keep the sawn ends immovable, as in a fracture, but to prevent the turning outwards of the limb by those muscles that have an origin from the pelvis.

The operation thus performed is not at all difficult, and seems to promise a certain amount of improvement of the deformity, which for six years has rendered the patient a helpless cripple.

TRANSLATIONS.

INFLUENCE OF THE NERVOUS SYSTEM UPON THE PHENOMENA OF PREGNANCY AND PARTURITION (Prof. Goltz and Dr. A. Freusberg: *Archiv für Phys.*, ix., 1874).—"On the 17th of December, 1873, a section of the spinal cord of a bitch nine months of age was made, and on the 28th the left sciatic nerve was also divided. From May, 1874, the animal was perfectly well, with the exception of the paralysis, was intelligent, and gained in weight, although it was proved with certainty that no transmission of nervous force took place along the cord. About the end of May the bitch became pregnant, and on the 10th of August gave birth to a strong living pup, which she cleaned by licking and then ate the placenta. A second and a third pup, both of which were dead, were afterwards taken from her, and by her treated in the same way as the first, which was born alive. During labor rhythmical flexion and extension of the hind legs were observed, and these evidently occurred in connection with labor-pains. By the touch contraction of the inner muscular tissues of the pelvis could be noted, but the vagina itself remained uncontracted. After delivery the bitch refused food, and died on the 12th of the month from peritonitis, consequent upon a perforation of the vagina. The body was examined after death, and the cut ends of the cord found to be one centimetre apart, the lower isolated portion of the cord being of normal size."

Fritsch (*Jahrbücher*, 1875), remarking upon this, says that as the ovaries were intact in this case it is conceivable that the animal should go into heat. During this time she treated the dog which she had previously driven from her in a friendly manner, but this disposition would not have been seen had the ovaries been extirpated. The condition of the brain must therefore be affected by the presence or absence of the ovary, and in this case, as the spinal cord was cut in the lumbar region, if these impressions were conveyed by this route, the sympathetic fibres must have joined the cord above that region. It appears more probable that while animals are in heat characteristic matters enter the blood, and thus act upon the brain. There is nothing strange in the idea of impregnation without sensation, since women will conceive when stunned. The development of distant organs is often dependent upon the presence of the essential parts of the genital organs. Körner has asserted that the motor fibres of the uterus have their

origin from the cord about the last dorsal vertebra, and run downwards along the aorta, and these fibres would not have been injured in this experiment. But it is not probable that the entire act of parturition is dependent upon the brain, as other fibres have their origin about the third and fourth lumbar vertebrae. Moreover, in this case the external muscles took part, and this could not have been due to impulses from the brain, but must depend upon a nervous centre in the lumbar region of the spinal cord. This centre may perhaps extend over the entire cord, so that when this is cut both portions may have power to act as long as the nerve-fibres which convey impulses outward from it exist. In the case of a primipara, aged twenty-four, in whom, in the sixth or seventh month of pregnancy, the third and fourth cervical vertebrae were fractured, there was entire paralysis of sensation and motion below the seat of the injury, but still labor-pains occurred, which were not felt by her, but were powerful enough to cause the birth of a dead child. The phenomena of this case would also tend to prove the existence of an independent centre in the cord. W. A.

DIPHTHERIA OF A VACCINATION PUSTULE FOLLOWED BY GENERAL DIPHTHERIA (Dr. Ludwig Letzerich: *Virchow's Archiv*, B. lxi.).—The patient in this case was a child aged four months, which, until vaccination, had been perfectly healthy. On the thirteenth day after this operation was performed, an erysipelatous swelling developed itself about the wound, and spread with great rapidity over the entire body. (Edema soon appeared, followed by icterus and petechial exudations, and death took place on the twelfth day of the disease, the twenty-fifth from the day on which vaccination was performed. At the post-mortem examination lesions characteristic of diphtheria were found, and the question arose whether the lymph which had been used had been the conveyer of the disease, or whether the diphtheria had been contracted at the wound, but at a later period. The fact that diphtheria in such cases makes its appearance some days after vaccination has been performed would seem to indicate that it is not inoculated with the lymph; but, to make this point more clear, experimental inoculations on animals were made. From these the following conclusions were drawn:

1. Vaccine which is infected with the organisms which are characteristic of diphtheria is not capable of causing vaccine pustules.

2. The inoculation of lymph which contains such organisms is rapidly followed by local deposits and general diphtheria.

And these experiments show especially:

1. That the lymph which was used in this case was not thus contaminated, or there would not have been a development of a vaccine pustule at the proper time.

2. That the local diphtheritic changes, followed by the disease itself, must be regarded as processes of secondary character. W. A.

DIABETES.—A complete cure of this affection is related in the *Bahia Medical Gazette*, by means of phenic acid, two and a half grains night and morning, in a vehicle of mint-water. The patient, a teacher of music, had been struck from his saddle by a falling tree. Trommer's test had shown a very large amount of glucose or grape sugar in the urine.—*The Doctor*, Aug. 1.

PHOTOGRAPHY IN MEDICINE (*The Lancet*, August, 1875).—Dr. Ultzman asserts that an eruption of small-pox had been made evident by photography twenty-four hours before it actually came out. Nothing could be seen on the face of the patient, but the negative plate showed stains in the face which perfectly resembled the variolous exanthem.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 21, 1875.

EDITORIAL.

A DANIEL COME TO JUDGMENT.

A CASE has recently been decided in London which is of enough general interest to make it worthy of brief recapitulation. The operation of tracheotomy was performed on a little boy who was lying at the point of death from diphtheritic croup and laryngeal obstruction. Owing to the professional duties of both the attending physician and the operator, they were unable to remain continually with the patient: so, as it was foreseen that in the course of the case there would be difficulty in keeping the artificial opening clear, the services of a physician who lived near were obtained. This gentleman, with his brother, a qualified practitioner, was in constant attendance for one hundred and thirty-two hours, during which time the tracheal tube became repeatedly blocked by secretion, and the child on several occasions narrowly escaped suffocation, and was once brought back to life by artificial respiration, the natural breathing having entirely stopped. The case terminated in complete recovery, and an account was sent in at the rate of five guineas for every twenty-four hours of attendance. This was objected to, and was at once reduced to three guineas; but payment was still refused, no pretence being made, however, that the child's parents were unable to pay the sum demanded. The matter was taken to court, and was decided in favor of the physician, who obtained judgment for the full amount.

The *Lancet* looks upon this case as one of considerable importance, as affording a decision in which

what may be called the minimum fee for constant day and night attendance by a medical practitioner may be based.

It alludes in very complimentary terms to the summing up of the judge, who spoke of the difficulties of carrying out the details of treatment in a terribly infectious disease for one hundred and thirty-two hours, seeing at the same time the peril of the patient, and hearing and sharing the anxieties of parents and friends.

He also told the jury that "in a judgment such as was before them, they must take into consideration not merely the time of the service rendered, but the importance of the service. He had calculated that for the duties performed the sum of two shillings and seven-pence per hour had been charged, and that a surgeon working night and day at this rate, in ordinary practice, would not earn more than a thousand a year; and it could hardly be expected that, for a service so purely exceptional as had here been rendered, a less than ordinary fee should be demanded."

Verily,

"Truth from his lips prevailed with double sway."

WE are glad to see, in the shape of a letter from Dr. William Pepper, a denial of the report which was published in some of the papers, to the effect that on the occasion of the accident at the Frankford Arsenal the physicians at the University Hospital had withheld their services until they had telegraphed to know whether they would be paid for them. Dr. Pepper states that they went at once to the scene of the accident, and that "the question as to payment was asked in a moment of hurried interview with the messenger, solely in regard to the means of transportation, by the senior resident surgeon of the hospital, a gentleman from Mobile, who was perfectly ignorant whether Bridesburg was five or fifty miles away." To those who are acquainted with the gentlemen in question this explanation is unnecessary; but we reprint it for the benefit of those members of the profession who may have seen the first report and not have noticed its contradiction.

ERGOT IN THE TREATMENT OF INSANITY (*The Medical Record*, June 26, 1875).—Dr. Edward C. Mann reports several cases of maniacal disease in which the free exhibition of ergot produced either a decided amelioration or a positive cure. He believes with Dr. Browne that it is eminently useful in recurrent mania, chronic mania with lucid intervals, and epileptic mania, and that its good effect is due to its power of re-establishing the equilibrium of the intra-cranial circulation which has been temporarily disturbed.

LEADING ARTICLES.

MASSAGE.

MASSAGE, or, in plain English, shampooing, has long been a recognized procedure in medical treatment, though until lately it has seldom been employed in a careful or systematic manner. The quacks, "bone-setters," "rubbers," and the like, have enjoyed nearly a monopoly of the practice until recently, when the subject has been brought once more to the notice of the profession in a series of able articles in various foreign journals.

It is the aim of the present communication to give, in a succinct form, some account of the various methods of employing massage, the diseases in which it has been found most efficacious, and the different modifications of the procedure most applicable to each class of affections. The writer is indebted for most of the facts embodied in this article to an admirable résumé of the recent literature of the subject by W. Berger.*

The various manipulations included under the term "massage" (from *μασσω*, to knead) comprise stroking or friction (*streichen*, *effleurage*); rubbing (*reiben*, *massage à friction*); kneading (*kneten*, *pétrissage*); percussion (*schlagen*, *klopfen*, *tapotement*). Any of these may be employed separately, or several in conjunction.

The first, stroking, is performed by passing the hand gently and slowly over the surface desired to be acted upon, the flattened palm pressing against the skin, and the motion being in a direction from periphery to centre,—that is, in the direction of the venous and lymphatic currents.

Rubbing is a form of massage more frequently employed than stroking: it is similar in every respect, excepting that the movements are more vigorous and are not confined to a single direction. Previous to rubbing, all hairs should be removed from the part to be operated upon, lest irritation and the formation of acute pustules should result, which, of course, would put an end to massage for the time being. Fat or oil is sometimes used with advantage in rubbing, and the fingers should be made to follow all the inequalities of the surface, being employed with an amount of force considerably greater than that used in stroking. Rubbing should be practised with both hands simultaneously; one may be moved in a horizontal or circular direction, while the other is impelled vertically. Perfect quiescence of the part operated upon is not necessary, nor even desirable.

Kneading is performed by seizing the part in the hand, raising it from the subjacent tissues, rubbing, rolling, or kneading it between the palms, or moving it to and fro on the parts beneath. These movements are to be alternated at times with brisk friction of the surface.

Under favorable circumstances, massage should be practised twice daily, with an interval of three to four hours between the manipulations. More frequent use

of the method is sometimes advisable, but is prevented by want of time. The length of time occupied by each "sitting" may vary from six to ten minutes on an average.

Massage, when used for the first time in a case, may give rise to more or less pain, which, however, ceases with the completion of the sitting. The feeling ordinarily experienced is that of general warmth, pliability, and invigoration of the part operated upon occasionally; while the skin is reddened, its temperature increased, and occasionally blue, green, or yellow discoloration is noticed. This discoloration does not in any way affect the progress of the case, and, in fact, disappears after repeated manipulations.

Among the advantages claimed for massage are these: it promotes absorption of effused material, accelerates the circulation, assuages pain, and reduces temperature.

The rationale of its effect in these directions may be explained, at least in part, as follows. Stroking and rubbing from the periphery towards the centre lead to a direct pressure upon the interstitial lymph-canals, and thus aid in carrying away the products of effusion. In addition, an increase in the rapidity of the vascular current is gained, and the rubbing excites the nerves (at least at first) in such a way as to cause contraction of the blood-vessels themselves. When the inflammatory process has gone a step farther, and stasis exists to a certain degree in the arteries, the stroking movement first arrests the flow for a moment and sends the arterial current backward, while accelerating that in the veins. Then, when this momentary pressure is removed, the vessels are filled again, the blood moved by *vis a tergo* overcomes the stasis, and the circulation becomes more active. Towards the end of the sitting a certain amount of hyperæmia of the vessels in the manipulated parts of course occurs. This, however, never amounts to actual stasis, since exit is made easy through the thoroughly emptied capillaries and veins, the muscular movements usually made by the patient after the manipulation aiding directly in promoting absorption. A more active circulation being now established in the whole vascular region, the capacity of the capillaries is increased, and absorption is also aided by diffusion. Massage also brings about absorption by its direct influence upon the lymphatics and capillaries: the swelling in the affected part goes down, the sensory nerves are freed from the tension and pressure to which they had been subjected, their irritability is abated by further manipulation, and the temperature of the locality operated upon is lowered.

In chronic inflammations, particularly in and about the joints, vigorous circular rubbing comes into play in addition to that from periphery to centre. This crushes the newly-formed blood-vessels in the hyperplastic tissues. The fluid portions of the extravasation being drained away by the pressed-out veins and lymphatics, the more solid portions deprived of nourishment proceed to retrograde metamorphosis, and are also gradually absorbed. The characteristic fungous granula-

* Schmidt's Jahrbücher, Bd. clxvi., 1875, p. 158.

tions of chronic joint-inflammation are removed in a similar manner. Thus the active circulation kept up not only by frequently-repeated manipulation but also by active muscular movements aids directly in causing absorption of effused material.

The various manipulations of massage act directly upon the nerves, causing at first increased sensibility, later diminishing this so that it may act in allaying morbidly increased irritability of the nerves.

The various manipulations connected with the procedure under consideration act directly upon the muscles. For the excitation of contractions in paretic or paralyzed muscles stroking and percussion are important means, and kneading has been proved to act powerfully in increasing the vitality of paralyzed and atrophied muscles.

The indications for massage are found principally in those conditions of disease in which hyperæmia, extravasations, exudations, hyperplasiæ, condensation and thickening of the tissues, or adhesions between sinews and their sheaths, exist. Especially is massage indicated when the products of inflammation are such as may enter the circulation without prejudice.

In diseases of the joints, it is particularly useful in the acute and chronic forms of synovitis, inflammations and extravasations in the neighborhood of joints and contractions, so long as these do not depend upon bony ankylosis. Among diseases of the muscles, it is particularly indicated in inflammations and rheumatic affections.

Among nervous affections, it is particularly indicated in neuralgias and paralyses of peripheral origin; in these massage has been proved most useful.

Massage has been used in dyspepsia to give tone to the muscular walls of the stomach, and to increase its secretion. It has also been employed with success in skin-diseases, accompanied by exudation and thickening of the corium, and finally in the formation of abscesses and mastitis.

Massage offers no prospect of success when the pathologic-anatomical nature of the morbid change itself places an invincible hindrance to the attainment of a favorable result. Thus, in diseases of the joints involving the bones or cartilages, primarily or secondarily; in otitis, osteomyelitis, or arthritis deformans; in the later stages of ankylosis with enlargement of the bones or organized connective-tissue growth; in disease of the joints with fractures, either extending into the articular cavity itself or in its immediate neighborhood, and in affections of the joints attended with supuration, it is naturally contra-indicated. Further, in advanced muscular atrophy of central origin, in neuralgias of central origin or dependent upon constitutional causes, nothing can be done by local treatment.

The general condition also may contra-indicate massage under certain circumstances; in many complicated acute and chronic diseases an improvement of the general condition must first be awaited before massage can be employed.

The indications for the use of the several manipula-

tions are different according to the method of action of the latter.

Stroking aids in the removal of lymph and inflammatory products by the vascular system. It is, therefore, useful in acute cases; for instance, in acute synovitis with recent inflammation of the soft parts, especially if these are red, swollen, hot, and sensitive. Occasionally in using stroking it may be necessary to continue the manipulation one-half to one hour, though a shorter time suffices in most cases. Under the influence of the operation the pain usually diminishes, and the swelling and heat subside. In chronic cases demanding the more violent use of other manipulations, stroking may be employed towards the end of the sitting to guard against the swelling so apt to follow a severe rubbing.

By means of rubbing, newly-formed vessels are crushed and the tissues placed in a position to react actively, the circulation aroused, and absorption aided. It is principally indicated in chronic synovitis and perisynovitis, effusion into the sheaths of the tendons, chronic infiltration of the muscles, and similar affections.

Kneading is to be employed in inflammatory swelling of the muscles, in chronic muscular rheumatism, in "ischias," where the muscles in the neighborhood of the nerve are often affected; also in fatigue of the muscles, in order to avoid the occurrence of myositis.

Percussion is used at times for the purpose of exciting nervous action, at other times with a view to allaying it. In neuralgias this form of massage may be employed with the aid of a percussion-hammer of rubber or ivory.

It is easily understood that the particular kind of massage to be used in one case or in one class of cases may be quite different from that which would be appropriate under other circumstances. Thus, in articular affections the lighter methods are to be used when the trouble is a superficial one, the more forcible methods when, as in hip-joint inflammation, the disease is deeply seated.

The soft tissues about the diseased joint in articular affections must also come in for their share of manipulation, for by this means the neighboring vessels will be influenced, partly in a direct manner as heretofore described, partly in an indirect manner through the vaso-motor nerves.

In the treatment of articular affections massage is superior as an instrument of resorption to the bandage, for the latter compresses the subcutaneous veins, causing stasis and even œdema, while massage does not allow of stasis. It was formerly believed that massage could only be used in chronic articular affections; but it is now known that the milder methods may be used to advantage even in acute cases.

Massage has been found useful in acute and chronic synovitis serosa, and in perisynovitis. In the hyperplastic forms of synovitis it is to be used in a more forcible manner, particularly when the perisynovial parts are much thickened.

In these cases the rationale is, according to Kiör, as

follows. The newly-formed connective tissue changes into cicatricial tissue; by the contraction of the latter the lumina of the newly-formed blood-vessels are closed, their walls become atrophied, the more remote vessels are more or less emptied of their contents and their elastic walls contracted. At the same time, by continued manipulation the thinner blood-vessels are crushed. Of course, manipulation so rough as to produce this effect involves a certain amount of acute inflammation and exudation, but the latter is rapidly absorbed, while the torn vessels become atrophied. It is understood that in manipulations of this kind care must be taken not to excite too much inflammation. This may be avoided by only operating upon a portion of the diseased structure at any one sitting.

In synovitis pannosa massage has proved useful, and also in chronic, and even acute, articular rheumatism. Of course, in the earlier stages of the latter, massage will do no good, but in a later stage, when the trouble really seems a local one, gentle rubbing and manipulation have frequently proved of the utmost service.

In affections of the muscular system, myositis, rheumatism, and inflammation of the sheaths of the tendons, massage is highly spoken of by various writers. In writer's cramp it has been used in connection with injections of strychnia; but the good effect in these cases was in all probability due to the latter.

In various affections of the nerves, neuralgias, and particularly ischias, where tumor or degeneration is not the cause, massage produces the happiest effect. It is in the latter class of cases that kneading and percussion are particularly useful. In certain peripheral paralyses massage has often acted very favorably, and in these cases, also, percussion is the preferable form.

In telangiectasis Metzger has used massage with good effect. The method of its employment is as follows. A finger of one hand is laid upon the efferent vein, thus causing the capillaries of the affected part to become filled with blood. These are then suddenly squeezed together with considerable force, with the effect of rupturing some of the capillary walls. The process is repeated at subsequent sittings, proceeding from the periphery towards the centre. The rupture of the capillaries thus brought about results in extravasation of blood, and subsequently in insignificant inflammation. The extravasation disappears spontaneously, but its recession may be hastened by rubbing in the direction of the lymphatic current. The inflammation is not likely to be serious if only a portion of the growth is operated upon at a time.

Metzger has used massage to prevent the formation of abscesses, and this method has also been employed in mastitis, in bony tumors, in corneal exudations, and leukoma. It has been suggested in affections of the uterus.

What the actual value of massage as a remedial agency may be it is difficult as yet to say, but in the hands of qualified persons it undoubtedly must prove a valuable adjuvant in many cases of chronic and intractable disease. It should, however, be taken entirely

out of the regions of charlatanism, and intrusted only to those educated to use it rightly. There is a certain amount of physiological and anatomical knowledge necessary for the employment of the method, but not more than can be acquired by a skilful and intelligent nurse; and it is to be hoped that in time the ability to perform massage will be one of the recognized accomplishments of a properly-educated attendant upon the sick.

CORRESPONDENCE.

NEW YORK, August 7, 1875.

THE following case of *atresia vaginae* completes our record of Prof. Thomas's recent operations at the Woman's Hospital. The patient was a lady twenty-two years of age, who was well developed, but had never menstruated. She said that when she was fourteen she began to have pains in the back and in the lower part of the abdomen regularly once a month. This continued for about ten months, when it ceased, but was succeeded by a feeling of faintness, sometimes accompanied by headache, which still recurs pretty regularly every month. On examination of the vulva there was no appearance whatever of anything like a vagina. Before proceeding to operate, Dr. Thomas pointed out the danger of endometritis or peritonitis being occasioned by the sudden evacuation of menstrual blood which has been for a long time imprisoned in the uterus or its appendages.

The uterus and Fallopian tubes are sometimes distended so greatly by this fluid, and thereby rendered so acutely sensitive, that the admission of air may produce dangerous or even fatal septicæmia. At the same time, he spoke of the danger of delaying operative interference during the period of menstrual activity, in consequence of which lives have not infrequently been destroyed by rupture of the Fallopian tubes, and even of the uterus itself, from distention by menstrual blood. In one instance of atresia he had seen a hæmatocele the size of an infant's head result from regurgitation of blood through the tubes into the peritoneal cavity. Should these accidents not occur, the retention of the menstrual flow is likely to occasion grave nervous and cerebral symptoms.

In the operation for atresia vaginae, Dr. Thomas now entirely discards the knife, scissors, and all other cutting instruments, except in its very first stage. He uses the scissors simply to clip out a small portion of mucous membrane at the point where the mouth of the vagina ought to be, and for the rest of the operation pursues Graily Hewitt's plan of using the finger exclusively. He has found this method infinitely less troublesome and tedious, as well as less dangerous, than the old procedure of dividing the tissues with the scalpel or scissors. An assistant holds a sound in the bladder, and the operator keeps the forefinger of his other hand in the rectum. It is simply a matter of tearing through the connective tissue which separates the bladder from the

rectum, and there is but little danger, if proper care is observed, of perforating with the finger either the bladder in front, the rectum behind, or the peritoneum above.

When Dr. Thomas was in the habit of employing the knife and scissors in this operation, he cut through into Douglas's cul-de-sac on one occasion, but no bad results followed,—which seemed to confirm the observations of Carl Braun, of Vienna, who now considers it a very trifling accident when he takes out a piece of the peritoneum in amputating the cervix and in other operations. In the course of a few minutes Dr. Thomas had worked his finger up to its whole length in the newly-made vaginal canal, but now, when this was accomplished, he was not able to detect the slightest trace of either uterus or ovaries. In this connection it may be well to state that previous to the operation she had been thoroughly examined by the rectal touch, according to the method of Simond, and this had also proved negative in its results. Still, as Dr. Thomas remarked, a vagina will be a convenient thing for the patient to have in case she should ever marry. Before she was removed from the table, a vaginal dilator, such as Sims recommends in cases of vaginismus, was inserted.

This consists simply of a glass plug three inches long, slightly conical, open at one end and closed at the other, and about an inch in diameter. It is to be retained in position by a T-bandage, and will have to be worn for a considerable period.

The New York Diet Kitchen Society have published their second annual report for the year ending March 31, 1875. The objects of the Association are now well understood and appreciated by the charitable public. They are all practical, originating in the conception that food properly prepared is, in many cases, the best medicine, acting both as curative and preventive of the worst form of disease and contagion among the poor. The first kitchen, on Second Avenue, working in the Demilt Dispensary District, has for nearly two years answered all the requirements made by the physicians of the Dispensary upon it.

In a letter to the managers, Dr. Edward Darken, house-physician to the Demilt, says, "The working of the Diet Kitchen in this district has been most satisfactory (indeed, I have been surprised at the promptness with which demands upon the kitchen have been always met by your efficient matron), and the good done has been very great. You are to be congratulated upon the fact that you and all donors of time and money towards this object have the best possible evidence that all your beneficiaries are deserving." The managers truly say that they need no greater encouragement in their work or more eloquent argument to enlist benevolence; for when to poverty sickness is added, there is seen the strongest appeal that human suffering and helplessness can make to charity. Many of the expenses incidental to starting the machinery of a new effort were not repeated in their second year, nor will the same outlay be necessary in the establishment of other kitchens, all centring about the parent kitchen,

and dependent upon it in many respects. No false economy, however, has been practised in the selection of the food-material. The very best has always been purchased, and a skilful cook employed for its proper preparation; so that it passes into the hands of the physicians an ally to their medicines that can be depended upon. The amount of food prepared and supplied varies, of course, with the season of the year and the prevalence of disease; but the calls upon the kitchen have more than doubled since the last year's report, the average daily number of patients during the winter being thirty. The managers report that with the surplus in the treasury, and the assistance of seven hundred and fifty dollars received from the Board of Apportionment, they felt able to spread their good work and establish a second kitchen. The Northwestern Dispensary District was chosen as the one representing the interests of the west side of the city, and on March 19 the new kitchen, under the charge of its Directress, Mrs. Wm. H. Wickham (wife of the Mayor), was opened at 438 West Thirty-Sixth Street.

The managers further express the hope that with each recurring annual report they will be able to announce the opening of at least one more kitchen, until there shall be no dispensary district in the city where this efficient aid to its beneficent work shall be wanting. From their present experience they believe that the total annual expense of maintaining kitchens throughout the city in accordance with the original plan of Dr. C. H. Atwater, who devised the scheme on which the Society was established, will not exceed fifteen hundred dollars for each kitchen, or for the whole city not more than twelve thousand dollars.

Owing to the bitterness of the past winter, and the increasing number of patients to be visited, it was found that the ladies of the Visiting Committee were unable to perform that work without aid, and a competent person for the purpose was employed to assist them, at a very trifling monthly expense to the Society.

A sewing society, also organized among the ladies to provide flannels and other articles of clothing for the patients of the kitchen, has provided such garments as have been needed in cases of destitute sickness. In concluding their report, the managers say, "What can more loudly appeal to benevolence, and even to selfishness, than such an institution as this? For it is largely by the aid of the filthy and insufficient food which poverty provides, and by which nature is disabled, that disease is all-powerful to hold such an undisputed course in our crowded streets and to become such a fearful scourge to our great city. And now and then an ungentle reminder for charity is sent out of the narrow streets into the broad avenues, as scarlet fever and diphtheria emerge from the places where they have been nourished into epidemics, and demand at our own doors a ransom that would have been gladly redeemed a thousand times by the 'cup of cold water,' or, in the diet expression, the bowl of beef-tea, by which their ravages might have been checked at the outset."

The Directors of the Demilt District Kitchen re-

port the number of patients during the year 466, and the various articles were dispensed in the following quantities: milk, 7606 pints; beef-tea, 3317 pints; rice, 423½ pounds (cooked); oat-meal, 305 pints (cooked); farina, 18 pounds (cooked); barley, 13½ pints (cooked); hominy, 10½ ounces (cooked); eggs, 256; milk-punch, 126 ounces; brandy, 46 ounces; soup, 48 pints.

The elegant new floating hospital of St. John's Guild made its trial trip on the 19th of July, with a number of invited guests on board. It is the largest barge ever seen in the waters of New York, and is two hundred and fifteen feet long, with forty feet breadth of beam, and ten feet depth of hold. It has three decks, of which the upper is a grand promenade-deck (covered), of almost the entire length and width of the vessel, where the patients have the full benefit of the sea-breeze, there being nothing in any part to intercept its current. The main deck contains two wards, each forty feet in length, and a spacious reception-room for those in charge of the sick. In the hold, which is admirably lighted and ventilated, is a dining-room where one thousand mothers and children can eat at the same time. There are also a convenient kitchen, store-rooms, ice-house, closets, etc., so that the whole is admirably adapted for its purposes.

The cost of the vessel was about twenty thousand dollars; more than one-half of which has already been paid. On the evening of the 20th a grand moon-light excursion was given by the St. John's Guild on the new barge, and a handsome addition is said to have been made to the floating hospital fund by the proceeds. The first regular trip of the season with the sick children on board was made on the following Tuesday, and since then trips are made on Tuesday, Thursday, and Saturday of each week. The boat starts from the foot of Twenty-Third Street, East River, at 8 o'clock A.M., and, after making a number of landings, finally leaves the foot of Thirty-Fourth Street, North River, at 9 o'clock, returning in time to make its last landing by 6 o'clock P.M.

The tickets for these excursions are given out by the members of St. John's Guild and by physicians generally at the various dispensaries and hospitals; and each mother is allowed to take all her children, whether sick or not, who are under eight years of age. Medical attendance is afforded by a number of physicians, who volunteer their services as occasion requires, Dr. William Thurman being the chief medical adviser.

As the sale of Paris green is now very general, and suicide by the swallowing of this material has become alarmingly frequent, the Board of Health has passed the following resolution:

"That the Sanitary Superintendent be and he is hereby directed to enforce Section 15 of the Sanitary Code, and to cause a printed notice of the same, and of the State law with regard to the sale of poisons, to be served upon all persons who keep this and other poisonous materials for sale."

The section referred to prohibits the sale of Paris

green except under the regulations enforced against all druggists as to the sale of prussic acid, arsenic, and other poisons, and its enforcement will prevent its being sold carelessly in paint-shops, etc., in the future.

The American Otological Society and the American Ophthalmological Society both held their annual meetings at Newport in the latter part of July, and the members thus had an opportunity of enjoying the pleasures of that charming seaside resort, as well as of contributing to the advancement of their respective sciences. Among those present were Drs. Strawbridge, Barker, and William Thomson, of Philadelphia; Blake, Dix, and J. Orne Green, of Boston; and Agnew, Knapp, Noyes, Matthewson, Prout, Thomas R. Pooley, O. D. Pomeroy, Roosa, Sexton, and A. H. Buck, of New York and Brooklyn.

Among the more important papers read before the Otological Society were, "Intra-tympanic Pressure," by Dr. Buck; "Otitis Media Hæmorrhagica," by Dr. Pomeroy; "Angioma of the Auricle," by Dr. Kipp; and "Experiments on the Effects of Quinine on the Ear," by Dr. Roosa. The Society originated at Newport in 1867, and now numbers about sixty members.

Probably the most interesting case reported at the Ophthalmological Society was one of Dr. Knapp's, in which he removed a tumor of the optic nerve (scirrhous), involving its whole intra-orbital tract, without ablation of the eyeball. It is believed that this is the first time that this operation has been performed; and one of the principal points of interest in connection with it is the demonstration to how great an extent the optic nerve and muscles of the eye will admit of being stretched. Before the operation the tumor occasioned very great pain and deformity, forcing the ball forward and downward; but the patient is now in excellent health, and there is no evidence of any return of the disease or of cancerous deposit in any other part of the body. This Society was organized eleven years ago, in New York, the late Prof. Delafield being its originator, and now has about seventy members in different parts of the country, selected from those of the profession specially interested in ophthalmic science and art. PERTINAX.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JUNE 24, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

DR. EDWARD L. PARKS presented, for Dr. F. F. MAURY, the following specimens, and read their histories:

"*Larynx of a man strangled with a piece of meat, together with the bolus.*"

"P. M., about 50 years of age, after a hurried dinner, seated himself in an eating-saloon. Soon violent symptoms of strangulation followed, which failed to dislodge the foreign body, and in about five or ten minutes he died."

"The notes of the examination are, 'External ap-

pearances normal, except a slight scratch over left eye. Slight post-mortem discoloration. Pupils natural.

"The trachea and larynx being removed, a large bolus of meat, weighing about 3iv to 3vi , was found impacted in the larynx."

"Punctured wound of chest-wall, with incised wound of aorta."

"F. R. was stabbed in the back with a long, pointed knife. He fell upon the floor, blood poured plentifully from the wound, and in a very short time, probably not more than three minutes, he was dead. There is no history of a stab elsewhere, though another was found after death.

"The notes of the examination are,—

"Post-mortem discoloration on the posterior portion of the body. A wound was seen two inches above the inferior angle of the left scapula, and two and a half inches from the median line. This wound was three-fourths of an inch in length, and ran obliquely downwards and outwards. On removing the flap of skin covering this part of the body, a large coagulum was observed lying between the skin and underlying tissues. The wound in this position was one inch long, and one-half inch from the spine, and penetrated the chest between the seventh and eighth ribs. The lower border of the seventh rib was sharp, caused by contact of the wounding instrument. On the anterior left aspect of the body, about six inches above the anterior superior spinous process of the ilium, and between the tenth and eleventh ribs, a wound was found, extending obliquely downwards and inwards. On removing the flap of skin covering this portion of the body, the external wound was found to correspond to a point immediately above the tenth rib, and about four inches from its anterior free margin. It had no connection with the thoracic or abdominal cavities. Had this wound penetrated deeper it would have passed into the abdominal cavity under the diaphragm.

"There was an escape of bloody serum from the mouth, but no marks of violence about the head.

"Pupils somewhat dilated, balls of eyes normal.

"Firm pleural adhesions over both lungs, of old standing. Lung-substance normal. The left pleural cavity contained a clot, as well as some fluid blood.

"Pericardium firmly adherent to the heart. Heart normal.

"An incised wound was found to sever almost the half of the ascending arch of the aorta, in a line directly opposite the seventh and eighth ribs, and opposite the external wound on the posterior left lateral part of the body, as before described."

"Fracture of the cranium."

"T. W., 37 years old, born in Scotland, was brought, intoxicated, to the Philadelphia Hospital the 2d day of last May. When seen by the resident physician at 2.30 in the afternoon, he was asleep, and was not aroused. When seen again in the evening of the same day, he was still unconscious. Pulse 84, pupils slightly contracted. 'He appeared,' writes the resident physician, 'like one who had been drinking to excess and engaged in a drunken brawl.'

"He remained unconscious till the evening of the next day (May 3), when he gave his name, complained of headache, and answered some questions intelligently, though he could not tell how he had been hurt. There was much tenderness over the whole surface of the head. Pupils continued contracted, as they had been since his admission. There was an effusion of blood into both eyes, around the orbits, and over the right mastoid process.

"In the afternoon of Tuesday, 4th, he began to relapse into unconsciousness.

"Wednesday, 5th, he was quite conscious, and complained of a severe headache.

"Thursday, 6th, he complained of severe pain, radiating from the temples over the forehead. His mind was clear, and he had perfect use of all his limbs. His pulse had been gradually falling since his admission, and on the evening of this day was 54 beats a minute; respiration, 18; temperature, 98°.

"Friday, 7th, morning, his hands and feet were cold, pulse 50, and there was slight ptosis. Great restlessness during the day. In the forenoon he lost control of his sphincters. In the afternoon he became quite unconscious. At noon his temperature was 100°; at 7 o'clock in the evening his temperature was 102°, pulse 98, respiration 26, with complete loss of motion and sensation.

"He died at 8.30 P.M., five days after admission.

"When first seen, he was ordered fifteen grains of blue mass. Subsequently, blood was twice taken by cups from the back of the neck and from the temples, with marked relief each time. Blisters and ice were also used.

"At the coroner's inquest, it was ascertained that he was pushed violently backwards from the door of a drinking-saloon, and fell, striking his head against the pavement.

"From the notes of the post-mortem examination we select the following:

"On removal of scalp, crown was seen to be discolored by blood. Temporal fascia of left side was injected, also the whole posterior aspect between scalp and pericardium.

"A fracture was seen, which commenced at centre of skull, above the external occipital protuberance, and passed irregularly but directly to right side of skull, ending at junction of squamous portion of temporal bone. There was a free escape of bloody serum before removing the skull-cap. After removal of skull-cap, the fracture was found to traverse the skull from the inferior angle of the parietal bone of one side to that of the other. The length of the fracture, by actual measurement, was twelve inches.

"Brain was injected, and clots found in its substance, and a large coagulum was found in the anterior portion of the cranial cavity. A clot on the left side was very adherent, and was semi-organized.

"The ventricles were normal. There were evidences of softening around the seat of injury; also a large abscess on left side.

"Cerebellum normal.

"Cause of death, fracture of skull, as described, followed by an effusion of blood into the cranial cavity."

"This case is valuable for several reasons: the length of the fracture, and the symmetry of the injuries to each parietal bone. Though strongly suspected, the fracture was not distinctly recognized during the life of the patient. Nor should we expect otherwise, since the clear-cut edges were held in close apposition by the scalp, occipito-frontalis muscle, temporal fascia, and periosteum, aiding the natural position of the bones. No crepitus, preternatural mobility, or deformity was to be found to point out that there was a fracture."

Gunshot wound of the eye—Excision of the eyeball.

Dr. JOHN ASHHURST, JR., exhibited an eyeball, removed a few hours before from a colored man, 38 years of age, who entered the Episcopal Hospital on May 30, 1875, suffering from a gunshot wound of the left upper eyelid and eye. Vision being lost, and the eye manifestly disorganized and moreover very painful, excision was resorted to.

The specimen was referred to Dr. W. F. Norris, as a special committee.

Dr. ASHHURST also exhibited a specimen of *rupture of the external iliac artery*, and read a history of the case, which is published in the current number of the *Times*.

Fibroid tumor of the uterus.

Dr. JAMES TYSON presented the specimen, for Dr. FRANCIS L. HAYNES, who furnished the following history:

"Mary M., aged 32, was treated for uterine disease in 1873, at the University Dispensary; among other means, sponge tents were employed. Receiving no benefit, she discontinued treatment for a time, and finally came under the charge of Dr. H. in October, 1873. A subperitoneal fibroid was detected by bimanual palpation. Under the internal administration of fluid extract of ergot, the flooding (which was her principal symptom) rapidly diminished, and in a short time she considered herself well. Examination revealed no change in the fibroid.

"The patient was now lost sight of until June 5, 1875, when Dr. H. was called to attend her, and found her in a collapsed condition, and suffering from intense abdominal pain, with constant vomiting. A strangulated inguinal hernia was discovered. She had been treated for 'cramps' by a homœopathic physician for eighteen hours previously. The hernia was reduced, and one-half grain of morphia given hypodermically. The vomiting and pain immediately ceased, but the patient never reacted, and died after twenty-four hours' illness.

"On post-mortem examination, the intestines were intensely congested, and presented a pinched appearance at one point, showing the site of the hernia. About four ounces of bloody serum were found in the pelvic cavity, with other evidences of local peritonitis. The fibroid tumor had evidently increased in size since 1873. The right Fallopian tube was dilated at its extremity, where it presented a small opening, from which was issuing a fluid of a tarry appearance.

"It was impossible to learn the immediate previous history of the patient; but it was known that she was menstruating at the time of her death."

GLEANINGS FROM OUR EXCHANGES.

A SPEEDY METHOD IN ASPHYXIA (*The Medical Record*, July 31, 1875).—Dr. Harvey L. Byrd believes that the following method will be found a highly valuable addition to our list of remedies in the asphyxia of children, and also for the relief of that condition in the adult, when properly applied:

Bring the *ulnar* sides of the hands near together, with the palmar surfaces locking vertically, and place them beneath the back of the infant, so that the extended thumbs may aid, as far as possible, in sustaining the vertex and inferior extremities; then, keeping the *ulnar borders* near together so as to form a fulcrum, the radial borders or sides are simultaneously depressed to as great an extent as practicable—say forty-five degrees—below the horizontal line, and then gradually pronated or elevated to as many degrees *above* that line, thus facilitating the escape of air drawn into the lungs during the downward movement of the head and chest. Or the hands are placed as at first, and passed *beneath* the body of the child,—on its back; and the superior and inferior extremities farthest from the operator seized, one by each hand, near the trunk,—the *ulnar borders* of the hands and wrists forming the fulcrum,—the head of the child being kept at a proper axis with the movements of the chest by the hands of an assistant, and

the depression and elevation of the head and lower extremities proceeded with as already described. These alternate depressions and elevations of the two extremities, performed in a regular and gentle manner, and repeated at proper intervals, seldom fail in establishing respiration where it is possible of accomplishment. The occasional dashing of cold water on the epigastrium during the *descent* of the head and chest will hasten respiration where the first few movements fail in its establishment. It is important that the head be kept, as far as practicable, from too much *lateral* movement, and not permitted to depart considerably from its *antero-posterior* axis with the vertebral column during the continuance of the process. To this end, in a critical case, the hands of an assistant may be brought into requisition. The importance of these remarks will be apparent to intelligent readers on a moment's reflection. No impediment should be *permitted* in the way of *free entrance* of air into the lungs during the *downward* movement of the head. And it is scarcely less important that no obstruction should prevent the *escape* of air during the *upward* movement of the head and chest.

LOCALIZATION OF FUNCTIONS IN THE BRAIN (*The Boston Medical and Surgical Journal*, July 29, 1875).—In a recent lecture, Dr. Brown-Séquard alluded to the various theories in the localization of functions in the brain, and to the fact that the character of the symptoms in brain-diseases is not in the least dependent upon the seat of the lesion, so that a lesion of the same part may produce a great variety of symptoms, while, on the other hand, the same symptoms may be due to the most various causes,—various not only as regards the kind but also the seat of the organic alteration. In view of these facts, he has been led to believe that lesions of the brain produce symptoms not by destroying the function of the part where they exist, but by exerting over distant parts either an inhibitory or an exciting influence, or, in other words, either by stopping an activity or by setting it in play. He concluded that if we survey all the facts brought forward to support the supposition that there are distinct psycho-motor centres in the brain, belonging to each set of muscles performing a distinct kind of movement, we find that it is impossible to admit that these centres occupy a separate, well-defined, and limited territory in some of the convolutions of the anterior and middle lobes of that organ; and we find also that the supposition that the nerve-cells endowed with each of the primary functions of the brain are disseminated through that organ, so that no local lesion or irritation can reach more than a part of those endowed with the same function or the same kind of activity, is supported by most of the known facts and out of harmony with none.

ABSCESS OF THE LIVER (*New York Medical Journal*, August, 1875).—Dr. S. W. Dana read before the Academy of Medicine the case of a man, æt. 52, who complained of severe pain over the region of the stomach, which was accompanied with vomiting. This improved for a time, but returned with greater severity. The case showed the marked influence of malarial poison, being characterized by chills every alternate day. Jaundice followed this malarial seizure, and was accompanied by an increase of pain over the liver. Physical examination showed the hepatic dulness to extend two inches below the level of the ribs. After this the patient began to improve, and the jaundice materially lessened, though the chills continued. He, however, afterwards relapsed and died. A few months before his death a tumor was detected below the ribs, which, as proved by the autopsy, was due to the formation of an abscess. When the post-mortem examination was made, the liver was found adherent to the abdominal parietes. Its lower margin extended two inches

below the margin of the ribs, but it was smaller than normal. The right lobe contained an abscess two and one-half inches in diameter, and one-half inch deep. The spleen and other lobes of the liver were normal. The points of interest in the case are mostly involved in obscurity. The cause of the abscess was unknown. There was nothing to show that disease existed in the intestines, and there was no history of injury to the liver.

SPINA BIFIDA SUCCESSFULLY TREATED BY PUNCTURE AND INJECTION (*The Indian Medical Gazette*, June 1, 1875).—Mr. G. W. Eate reports the case of an infant aged one month, the subject of spina bifida. Its general health was very poor, the lower limbs were paralyzed, and the tumor, the size of a large orange, and situated in the lumbar region, was ulcerated on its summit, and was extremely sensitive.

Pressure having been made on the tumor in the direction of the median line, and the space where the spinous processes of the vertebræ were wanting discovered, a trocar and canula were carefully introduced into the most depending position, and a quantity of clear fluid drawn off. The removal of this fluid was followed by collapse of the tumor. Into the sac, which, however, was not thoroughly emptied, two drachms of a solution of iodine (iodine, ten grains; iodide of potassium, thirty grains; glycerine, one ounce) were injected with an ordinary syringe, the solution being diffused throughout the sac by gentle manipulation; the canula having been withdrawn, the opening was closed by a strip of adhesive plaster, and a light compress of lint applied over the tumor.

The operation was well borne, and not a single bad symptom resulted from it. The tumor gradually diminished, until it is now about the size of a walnut. The child recovered with its general health greatly improved, with no pain in what remains of the tumor, and with some indications of strength in the lower limbs.

ARNICA IN ORCHITIS (*The British Medical Journal*, July 17, 1875).—Mr. H. G. Knaggs reports a method of treating orchitis, which, he says, he has for many years found very effective. It consists in the more or less constant application, while the patient is resting, of a lotion of tincture of arnica and water (one part of the former to six of the latter) to the affected organ; secondly, in rubbing in an embrocation composed of one-third or even one-half tincture of arnica and soap-liniment two or three times a day along the course of the spermatic cord; and thirdly, in the internal administration of seven-drop doses of tincture of arnica, combined, when there is febrile disturbance, with two-and-a-half-drop doses of Fleming's tincture of aconite and acetate of ammonia. This simple treatment, he says, generally cures the patient in a fortnight or less. In using our remedial agents of the above-named strength, there is little danger of causing cutaneous irritation; but it must be admitted that, while some skins will bear the constant application of even pure tincture of arnica for a considerable time, there are others which are inconceivably sensitive to the action of the drug. We must, therefore, be on the watch for any show of erysipeloid inflammation, in case such should occur.

QUINIA AS A STIMULANT TO THE PREGNANT UTERUS (*The Obstetrical Journal*, June, 1875).—Dr. Albert H. Smith sums up as follows the conclusions which he has adopted as regards the action of quinia upon the pregnant uterus:

1. Quinia has no inherent property of stimulating the gravid uterus to contraction, being inert as to any effect upon the womb in a quiescent state, and having no decided action in accidental labors at any period of gestation.

2. To its property as a general stimulant and pro-

moter of vital energy and functional activity, and to that alone, is due its influence upon the uterus in normal parturition, producing then no action peculiar to itself, but merely increasing the power of the uterus to expel its contents by its own natural method, converting what is a defective or even pathological action into a simple physiological process.

3. By availing ourselves of this power we may, by administering full doses of the sulphate of quinia at the onset of labor, favor the rapid and safe termination of what might otherwise be a tedious and exhausting work.

THE CHEAPER CINCHONA ALKALOIDS (*The Chicago Medical Journal*).—Dr. James S. Whitmire has for several years been employing in his practice the sulphates of cinchonina, quinidia, and cinchonidia, and even the residue—chinoidine. Cinchonina he has found unsuitable for use as an antiperiodic or antipyretic, because of its tendency to nauseate the stomach; but in smaller doses, in connection with the tincture of iron, he has found it useful as a general tonic. Forty grains of quinidia seemed to be equivalent to about twenty-five of quinine.

Dr. Whitmire is disposed to attribute to cinchonidia very nearly, if not quite, an equal therapeutic value with that of quinia, and in about the same doses, while its commercial value is only one-third that of the latter. Chinoidine he employs as a powder in three- to four-grain doses, after each meal, alternating it with Fowler's solution, and he has been very successful through its means in preventing the recurrence of intermittents.

SALICYLIC ACID IN DIPHTHERIA (*The Virginia Medical Monthly*, August, 1875).—Dr. Fonheim has treated with salicylic acid thirty-one patients having diphtheria. The severest cases were cured after eight days' treatment; the milder ones after two, three, and four days. Of the thirty-one cases, none died. There occurred no cases of diphtheritic inflammation of the kidneys, nor were there any cases of paralysis of the palate. In the severe cases, Dr. F. ordered the affected parts to be rubbed every three hours with a sponge dipped in a solution of salicylic acid, and to take as regularly a teaspoonful of the same solution. The formula used was: R Salicylic acid, 2 grammes (about 3ss); fountain water, 200 grammes (about 3vij); alcohol, q. s. (to make f3vij). Salicylic acid passes rapidly into the urine, and gives with chloride of iron a blue or violet reaction.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM AUGUST 10, 1875, TO AUGUST 16, 1875, INCLUSIVE.

BACHE, DALLAS, SURGEON.—Leave of absence extended one month. S. O. 45, Headquarters of the Army, August 10, 1875.

FORWOOD, W. H., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 155, Department of Texas, August 6, 1875; and leave extended two months. S. O. 46, Headquarters of the Army, August 12, 1875.

TAYLOR, B. D., ASSISTANT-SURGEON.—Assigned to duty at Fort Snelling, Minnesota. S. O. 149, Department of Dakota, August 5, 1875.

NEWLANDS, W. L., ASSISTANT-SURGEON.—Assigned to duty at Camp Halleck, Nevada. S. O. 87, Department of California, August 6, 1875.

TESSON, L. S., ASSISTANT-SURGEON.—Assigned to duty at the Military Prison, Fort Leavenworth, Kansas. S. O. 143, Department of the Missouri, August 9, 1875.

The following-named Assistant-Surgeons (recently appointed) are ordered to report by letter to the Commanding Generals of the Departments named, for assignment to duty:

CURTIS E. PRICE, Department of California.

H. S. TURRILL, Department of Texas.

JOS. V. PORTER, Department of the Gulf.

GEO. E. LORD, Department of Dakota.

S. O. 163, A. G. O., August 12, 1875.

SATURDAY, AUGUST 28, 1875.

ORIGINAL COMMUNICATIONS.

PARACENTESIS THORACIS.

A Lecture before the Oxford, Pa., Medical Society,

BY JAMES TYSON, M.D.,

Professor of Pathological Anatomy and Histology in the University of Pennsylvania; one of the Physicians to the Philadelphia Hospital, etc.

(Continued from page 740.)

THE quantity of fluid drawn from a chest in paracentesis is often enormous. Eighty ounces are not uncommon, and fifty to sixty are moderate amounts. At one time it was thought that only a part of the fluid should be drawn off at one sitting, lest syncope should supervene. This is now well known to be unfounded, and such partial evacuation is no longer thought necessary. But I myself prefer not to empty the chest completely, because I think I have observed that the violent pain, already alluded to as occurring after the tapping, is less likely to happen when some fluid is left behind, while its speedy disappearance by absorption is almost certain to take place if the inflammation has subsided, in consequence of diminished pressure upon the blood-vessels.

It sometimes happens that towards the close of the operation bloody serum and finally pure blood flow from the canula. This need not give any alarm, but the canula should be withdrawn and the operation discontinued, as the hemorrhage, which probably takes place from ruptured vessels in the false membrane, is best checked by the prompt coagulation and consequent pressure which thus result.

In terminating the operation, the canula is withdrawn and a piece of adhesive plaster of considerable size closely applied over the aperture and adjacent integuments. The edges of this may be overlapped by other pieces if desired. No other precautions are necessary, and under ordinary circumstances the opening is completely closed within twenty-four hours.

Not infrequently a fluid will reaccumulate, even if it be a simple serosity. This is more particularly the case when, as intimated, the inflammatory action has not subsided up to the time of tapping. Under these circumstances, it may be repeated as often as is necessary to secure the comfort of the patient and his final total relief. But if the fluid be a *purulent* one, it will almost invariably accumulate, and the difficult problem of getting permanently rid of an empyema is by no means successfully solved to-day. If it be known in advance to be an empyema, no precautions need be taken to keep the air from reaching the cavity; but, as this is scarcely ever certain the first time the tapping is done, one of the special apparatuses for aspiration may be used for this reason, and for the sake of the other advantages named with regard to them.

But suppose you have found an *empyema*, what will you do with it? After completely evacuating the chest, I have always after the first tapping closed

the opening as usual, although there is perhaps little good reason for this, so sure is the pus to reaccumulate. Still, besides the fact that there is some chance for a non-reaccumulation, it is sometimes well not to do too much at one time. The patient has been relieved, but the operation has been to him an alarming one, and I can conceive ordinarily no disadvantage in waiting for a reaccumulation. This having occurred, however, a sufficient opening must be made with a bistoury, and a drainage-tube introduced, such as I show you, with an incurvation downward, so as not to injure the lung. A stopper may be supplied by the instrument-maker, or one may be improvised. This being done, the accumulating fluid can be evacuated daily or as desired.

But you will not be likely in this way to get rid of it entirely, although in the patient I show you to-day I do not ascribe the gradual diminution of the flow to any other local treatment. Of course, I need not say to you that such cases require constitutional treatment of the most supporting and antipyretic kind. Nourishing food, alcohol, quinine, iron, and digitalis are pre-eminently indicated. But some local treatment is usual, the object of which is to excite cohesive inflammation between the costal and pneumal pleuræ. Hence it is of an irritating character, and the preparations of iodine are those usually employed. The strength cannot be unvarying, but will depend upon the irritability of the membrane. Trousseau, whose experience was so extended, recommended 50 grammes (771½ grains) of tincture of iodine (the French tincture is a little stronger than the American), 2 grammes (30.86 grains) of iodide of potassium, and 100 grammes (154.3 grains) of water, making a total of 152 grammes, or 4.88 ounces by weight. To this he added an equal quantity of tepid water, and injected the mixture into the chest-cavity, in which some fluid had been allowed to remain. After allowing this mixed fluid to come into contact with the chest-wall, a portion was drawn off, in order to obviate any toxic effects of the iodine, and the drainage-tube closed. On the next day the tube was opened, a portion of the fluid allowed to run out, and the injection repeated in the same manner. This was done for several days in succession, the quantity and strength varied according to circumstances,—pain, fetor, tendency to contraction, etc. Then the interval was made longer, once in two, three, or four days, taking care to empty the chest at least once in twenty-four hours. The treatment thus instituted is continued four, five, six months, and even longer. My own plan has been to use the tincture of iodine and Lugol's solution daily and at longer intervals, according to the degree of irritation; although I have never allowed the solution of iodine to remain longer than a few minutes to half an hour. My experience has not been very extensive, but it is impossible for me to say that the favorable results obtained are to be attributed to the iodine injections. Carbolic acid has been used for the same purpose, especially where there is extreme fetor.

This treatment of course involves the necessity of extreme deformity of the chest, due to external

atmospheric pressure. The lung being compressed into one corner of the thoracic cavity, and bound down there by adhesions, cannot at once return to its original position, while the evacuation of the fluid makes a vacuum, which, being only partially filled, allows the chest-walls to be pushed in by the external atmospheric pressure. This takes place the more rapidly and painlessly the younger and more pliant the chest-walls are, the more slowly and more painfully the older and more rigid those walls. It soon, however, becomes very marked under either circumstance. So too, in the course of time, if the case does well, this deformity gradually diminishes as the lung recovers its original volume, but months and even years are required for its completion, which perhaps occurs only in children.

In the case to be exhibited, some slight discharge continues daily through the fistulous opening which remains, and which we have been unable to cause to disappear entirely by the iodine injections; though it must be admitted that they have not been so perseveringly continued as is suggested by Trouseau, on account of the pain and discomfort which were occasioned by their use.

It remains to refer to the effect of removal of fluid from the chest upon the physical signs of auscultation and percussion. If the case be an acute one, or the effusion comparatively recent, if the evacuation be complete, dull percussion is replaced by resonance, and the respiratory sounds are again heard, including the vesicular murmur. But if the case happen to have been of some duration, and especially if the lung is much bound down and the pleuræ greatly thickened, it will often happen that the dulness is scarcely if at all diminished, and the vesicular murmur as faintly heard immediately after tapping. If the accumulation is kept down, however, the normal condition of affairs is gradually reproduced.

In conclusion, I desire to exhibit a couple of cases illustrating the two conditions under which the operation is most likely to be indicated.

Latent pleurisy with effusion—Paracentesis—Recovery.

I first saw J. H., aged 22, on the 5th of May, 1874, in a condition which proved to be the beginning of a typhoid fever. The disease passed through the various stages of a well-marked but not very severe form, and convalescence seemed decidedly established on May 20, so that I omitted a visit on the following day, which was Sunday. I saw him on Monday morning, when I was not impressed with anything unusual in his condition. While at dinner, however, on this day, I was summoned to see him on account of a feeling of extreme faintness and difficulty in breathing which had come over him. I auscultated his heart, found it beating rapidly, but exhibiting no sounds of valvular lesion. Not thinking of examining his chest further, I ascribed the condition to some temporary cause. On the next day, however, the symptoms continuing, I explored his chest, and found dulness from top to bottom of the left side, feeble and in places absent respiratory sounds, and diagnosed the presence of fluid. How long the effusion had been present it is impossible to say; but, from the sudden change in his symptoms, I am confident it was of rapid production, and did not exist in large amount prior to May 30.

Previous to his illness he had a slight hydrocele,

which increased rapidly, and became very troublesome by its size, during his illness. Diuretics were given for a few days without effect, when I urged tapping as the shortest route to recovery. I punctured the chest between the ninth and tenth ribs, on the line of the lower angle of the left scapula, and drew off between sixty and seventy ounces of limpid fluid, using the aspiration apparatus recommended to you and the exploring trocar only, as the fluid passed out so rapidly that I did not think it necessary to substitute it by a larger one.

From that time convalescence was rapid. The normal physical sounds rapidly returned, and in two weeks he was up and about. I am confident that as many months would have elapsed before he would have been as well under any other treatment, if, indeed, he would not have succumbed altogether; for his condition after the long attack of fever was one of extreme debility, which did not diminish until after the tapping. The lung entirely reoccupied its original situation, and there was never any subsequent deformity of his chest. To-day he is before you, exhibiting in the shape of physical signs of the chest no evidence of his extreme illness, in all respects a sound man.

The next case is one of unusual interest, being one of practical recovery from *empyema*, which I have watched for nearly three years, and which but for the procedure adopted would have been necessarily fatal. It illustrates, also, the effect, or want of effect, of a faithful trial of other treatment continued over a long period, and exhibits the gradual return of a much displaced heart and compressed lung to their normal relations.

Pleurisy with effusion—Empyema—Paracentesis—Recovery.

C. B., æt. 21, a native of Ireland, single, a shoemaker, moderate drinker. His parents are healthy, and his previous health was good. In December, 1871, he was attacked with a severe pain in the left breast, over the region of the heart, lasting about twelve hours. This was relieved by a mustard-plaster, but he was not able to go about for a week, and did not enjoy good health during the following year; complaining, however, of no pain, but merely of weakness.

On January 5, 1873, he contracted a bad cold, with pain in the left side, some cough and fever, for which he was admitted to the Philadelphia Hospital on January 7, 1873, having at the time of admission a pulse of 120, temperature 104°, and respirations 30.

January 22.—Inspection revealed evident filling up of intercostal spaces on the left side, below the nipple anteriorly, and laterally from axilla down. Percussion was dull throughout, back and front. Auscultation revealed marked tubal breathing immediately below the left clavicle, and the vesicular murmur was audible anteriorly only as far as the left nipple; below this it could not be heard, nor in the axilla. Over the upper part of the left lung, posteriorly, it was heard, but became indistinct as the base of the chest was approached, and finally disappeared. No vocal fremitus was appreciable anywhere over the left lung, except at its apex. The heart's impulse was seen to the right of the sternum, discernible from lower edge of second rib to upper edge of fifth, and extending to the right as far as the nipple line. There was also marked movement of the abdominal wall below the xyphoid cartilage, and in this situation also the first sound was heard most distinctly, and a very little higher up the second sound, which was loudest at the right edge of the sternum, and over the sternum itself, opposite the second interspace.

Treatment.—He was ordered the iodide of potassium (ten grains ter die), while the chest was to be kept painted with tincture of iodine.

February 7.—Says he is stronger, but complains more of dyspnoea, though we are unable to say, by inspection, that there is greater protrusion of the chest-walls. Physical signs remain as above noted. Has been taking the iodide faithfully, and has had the iodine applied externally more or less constantly.

March 10.—Removed twenty-seven and a half ounces of a sero-purulent fluid by a puncture by trocar and canula, between ninth and tenth ribs, in a line with angle of scapula. On microscopic examination the fluid was found to contain pus-cells in different stages of granular degeneration; also numerous compound granule-cells. The patient expressed himself greatly relieved after the operation, and said he felt as if he could lie down and sleep all day.

April 2.—Twenty-five and a half ounces of sero-purulent fluid were drained off with trocar and canula.

April 4.—Forty-eight hours after the tapping above mentioned, physical exploration revealed impulse of heart in same situation as previously noted; so also the heart-sounds. The respiratory sounds are audible as far as left nipple anteriorly, but not in the axilla; posteriorly, tubal in character, they are heard in supra-spinous fossa, and nearly normally in infra-spinous fossa; below the scapula they are feebly heard. Respiratory sounds continue supplemental on right side. Inspection shows less prominence in mammary region, though in other respects the conformation of side is not altered. Patient says he feels better than he has felt for nine months.

April 14.—General condition continues good, though he complains of being weak. Vesicular breathing is heard anteriorly only as far as nipple, and is not heard in axilla. It is heard distinctly in supra-spinous fossa, posteriorly, faintly over scapula below its spine, and very faintly, if at all, below angle of scapula. Ordered Basham's mixture, tablespoonful t. d., and iodide of potassium to be continued.

May 2.—He feels better and stronger than he did two weeks ago. Inspection reveals no change in appearance of chest. There is flat percussion throughout entire left thorax. Auscultation unchanged. Treatment continued as last noted.

May 17.—Complains of increased difficulty of breathing, for which ordered blister.

May 21.—Drew from his chest, before the class, forty-two ounces of sero-purulent fluid. Forty-eight hours later there was evident reduction in bulging of chest. At this time, also, dullness seemed slightly diminished; respiratory murmur was heard as far down as heart's dullness anteriorly, and throughout whole left chest posteriorly, but not in axilla.

June 2.—He is feverish, feeble, skin warm, pulse 99, respiratory murmur is no longer heard below left clavicle, being entirely replaced by bronchial breathing, and there is dullness throughout the chest.

June 8.—Drew from chest fifty ounces of sero-purulent fluid, which was much more consistent. This tapping gave him great relief.

June 11.—Chest again tapped, this time in the seventh interspace, and drainage-tube introduced, through which pus ran freely to the amount of fourteen ounces. During remainder of day it ran sixteen ounces; on the 13th, twenty-four ounces; on the 14th, forty-two ounces (last two ounces being of a pink color); on the 15th, five ounces, some pink color present; on the 16th, one ounce, pink disappeared. Has been losing strength and flesh during past ten days; but his pulse now is less rapid and skin cooler than immediately before drainage-tube was introduced. Pulse now is 99. On last date, the physical signs noted were as follows. There is such

hyper-resonance throughout the chest as of itself to suggest pneumothorax; there is an audible entrance and exit of air through the tube with both respiratory acts. Auscultation reveals metallic respiration over the whole chest anteriorly, in the axilla, and below the scapula posteriorly.

June 18.—General condition much better. Pulse 100, skin cool, temperature 98°. Physical condition can scarcely be said to be altered, although there is not so much pneumothorax.

June 30.—He is vastly better. The quantity of pus discharged has gradually diminished until yesterday, when only half an ounce of thin, turbid serum was discharged, and this morning nothing flowed from the canula. His temperature this morning is 98½°, and pulse 96. There is a slight evening exacerbation of both, temperature being 99°, and pulse 110. Has been allowed a farm-pass to-day.

July 2.—Discharge so much reduced that the canula was removed, and the opening closed with adhesive strips.

July 5.—Chest-walls are evidently bulging. Reopened the orifice, and five ounces of the thin, turbid fluid were discharged. This fluid, which is like that discharged during the last few days previous to the removal of the canula, has not the appearance of pus, being darker in hue and thinner.

July 14.—Discharge again purulent, but he continues doing well; has recently been ordered a pill of quinine, gr. j; digitalis, gr. ½; carbonate of iron, gr. ij.

July 23.—Does not appear quite so well; has a temperature of 100°, and a pulse of 120; last night pulse 106, and temperature 99°. Is disposed to be sleepy. The quantity of pus discharged is small, being but one ounce yesterday.

July 29.—Has revived from the drooping condition, and chest is discharging two ounces a day. Inspection reveals marked depression of the left chest anteriorly, below the clavicle; this is not noticeable laterally or posteriorly. An impulse is seen and felt in the second and third interspaces for two inches on each side of the sternum. It is most marked to the touch and to the eye in the third interspace, to the *right* of the sternum. On percussion the left chest is found resonant throughout anteriorly and in the axilla, while at the same time there is an absence of that hyper-resonance previously noticed on June 16. Posteriorly, however, throughout, the resonance is less marked than anteriorly and in the axilla. Auscultation reveals a total absence of metallic respiration, while in the upper part of the left chest, anteriorly and posteriorly, the air can be heard going into the finer bronchial tubules, attended, anteriorly, with some crepitation. Below the nipple anteriorly, and in the lower part of the axilla, a friction-sound is heard. Below the left scapula, broncho-vesicular breathing is heard. The first sound of heart is heard most distinctly at the lower third of the sternum, and the second sound is most distinctly heard at the second costal cartilage of the right side. At this situation a systolic murmur is also heard.

August 22.—Chest is resonant throughout, posteriorly as well as anteriorly, and air is undoubtedly heard entering the lungs throughout. The depression anteriorly continues, and is noticeable to the right of the sternum. Is discharging one-half ounce to one ounce of pus daily from the canula. Has occasional attacks of palpitation, of which digitalis relieves him (gtt. x, t. d.). Pulse 90.

October 8.—Is still improving, and gaining flesh decidedly. There has been no retraction of chest-wall during the last month. Pus discharging about as last noted. The impulse of the heart is now felt most distinctly one and a half inches to the right of, and one-half inch below, the left nipple, though an impulse is

still discernible at the right edge of sternum, directly opposite. The first sound is heard most distinctly at the situation of the apex-beat, and is accompanied by a shrill creak with every systole; as the ear is moved upwards towards the right of the sternum in the second interspace, where the second sound is heard most distinctly, this shrill noise disappears and is replaced by a murmur.

He was discharged during October, 1873. A week after his discharge he entered St. Joseph's Hospital, where he received, during five weeks, tonic treatment, but no injections into the cavity. During this period, he says, he grew gradually weaker, and lost appetite and flesh. At the end of the fifth week injections of carbohc acid were used. From the beginning of this treatment he improved in every respect, and the amount of pus discharged decreased from five ounces, the amount it had reached, to one-half ounce daily. It will be remembered, however, that the discharge fell to this amount in the Philadelphia Hospital without injections. He remained in St. Joseph's Hospital for seven months, when he was discharged. For four succeeding weeks he was in St. Mary's Hospital, where he received no injection treatment.

On June 19, 1874, he was readmitted to the Philadelphia Hospital, with a daily discharge of two ounces of pus. He was put on Basham's mixture, and quinine.

July 10.—Was injected with one ounce of solution containing pot. iodid., gr. ij; and iodine, gr. j; in water.

July 12.—Two ounces of the same solution were thrown in. Since the injection the discharge of pus has increased to three ounces.

August 21.—Injected f3ij of liq. iodin. comp. in four ounces of water.

October 20.—The above solution was used until it seemed to excite pain and produce a bloody discharge, without apparently diminishing the amount of fluid. It was then omitted altogether, and in the course of a few days the bloody discharge ceased, and then continued to discharge daily about two ounces of purulent matter, sometimes a little more, seldom less.

About October 10, recommended injecting him with a solution consisting of tr. iodinii f3i, water f3i. Of this fluid, about f3vj were injected daily, kept in for ten minutes, and then withdrawn with an aspirator, the fluid coming out with but little change in its appearance. The injection, when introduced, produces a tingling sensation, and excites no bloody discharge. The accumulated fluid is evacuated once a day through a canula, and amounts to about one and a half ounces. He feels perfectly well, only having a little dyspnœa when walking up and down stairs. His left chest is much contracted, and the apex-beat is a little to the right, and below the nipple. He is taking no remedies except tonics and good nourishment. To-day the strength of the injecting fluid is ordered to be increased to f3jss to the oz.

June 25, 1875.—Soon after the above note the injections were discontinued.

In appearance he is looking better than I have seen him since he has been in the house. He weighs about one hundred and twenty pounds. He is able to walk from the hospital to Third and Walnut Streets and return without fatigue, a distance of at least six miles. Observes no shortness of breath in walking on a level; but after ascending three flights of stairs, he observes some dyspnœa at the end of the third.

The opening made by paracentesis, apparently in the seventh interspace, and in a line with the anterior fold of the axilla, remains patulous, notwithstanding the removal of the tube last autumn. From this there is now discharged every evening, when the patient clears the canal with a probe, about one-half ounce of nearly transparent, bloodless, aqueous fluid, free from

odor. This quantity, since the warm weather has set in, is nearly double that discharged when it was cooler. This fluid has an acid reaction, specific gravity 1015, and on microscopic examination reveals numerous pus-corpuscles, with here and there a red blood-corpuscle.

The left chest is extremely retracted, and the ribs evidently drawn down so far as to include the first four ribs, the fifth rib of the two sides corresponding. The inferior third of the thoracic cage on the left side anteriorly is a little more bulging and extends a little lower than the corresponding part of the opposite side. Two impulses are distinctly observed on inspecting the chest, the more prominent at the left edge of the sternum, just below the third rib, this rib appearing to be drawn down, so as to correspond in situation with the fourth rib of the opposite side. On this rib is also placed the nipple, so that this point of more distinct impulse may be said to be an inch below and within the left nipple,—the normal situation. The second more feeble impulse is observed and felt about an inch and a half directly above the first, at the left edge of the sternum and at the second interspace; the second rib being also apparently drawn down as the third.

The first sound of the heart is heard most distinctly in the situation of the apex-beat and in its immediate vicinity, and is apparently normal. The second sound is heard most distinctly at the right edge of the sternum at the second interspace, or its immediate vicinity. The vesicular murmur is heard distinctly over the entire left lung anteriorly and posteriorly. Anteriorly, and in the axilla, resonance is perfect, but posteriorly it is still somewhat impaired, doubtless owing to thickened pleural membrane.

SHALL WE DISPENSE OUR MEDICINES?

BY THEODORE H. SEYFERT, M.D.

THE question as to whether we shall dispense our own medicines or not may appear to be of trivial importance, but in reality it is one demanding our consideration, since it directly affects the interests of the majority of our profession to a greater extent than many are aware of.

Whilst fully appreciating the objections that some gentlemen will urge against any proposition favoring a return to this custom, which is almost obsolete among regular practitioners in large communities, I would, nevertheless, like to direct attention to a few of the advantages connected therewith, hoping in this way to call forth an expression of opinion from those who are inclined to adopt the practice with certain restrictions. Putting aside all feeling of pride and of prejudice, let us ask what benefits are to be derived from assuming this duty which has been delegated to the apothecary.

In the first place, it will bring about a more desirable simplicity in the administration of medicines, thereby enabling us to acquire a more thorough knowledge of their therapeutic power.

An increased simplicity in prescribing has always marked the onward strides of our science. Apothecaries owe their existence to the fact that the busy practitioner of ancient times, who seemed to gauge the efficacy of his formulæ by the greatness of the number and the heterogeneous character of their ingredients, could not bestow sufficient attention upon his patients when he occupied himself with the laborious duty of compounding his own prescrip-

tions. Hence he employed others to perform this mechanical work. It may easily be imagined how little was understood of the therapeutic value of any one substance, when in its administration it was associated with many others of unlike character, and all mixed up together according to the whim of a prescriber who was influenced by the vagaries of his fancy or by erroneous science.

At the present day, however, polypharmacy is no longer the fashion, for it is in direct opposition to the acquisition of therapeutic knowledge, and contemporaneous with our progress is the tendency to a still greater simplicity in prescribing.

From many valuable drugs the skilful chemist has separated their active principles, and with these instruments of power we are every day becoming better acquainted as we wage our warfare against disease and death.

We are desirous of obtaining accurate information regarding the real value and the *modus operandi* of our medicines: therefore we make no elaborate formulæ, but exhibit them uncombined whenever we can consistently do so, in order that we may study their actions upon the system. It is not the multiplicity nor variety of tools which marks the skilful workman, but rather his thorough acquaintance with the few he has judiciously selected for the work before him.

Another important point for consideration is the effect produced upon the mind by dispensing medicines with our own hands. To possess the full confidence of a patient and his faith in our ability to cure, is to hold a therapeutic power of great importance. That this power is greatly lessened by the present system of dispensing is quite apparent, since by affording patients an opportunity to become familiar with our remedies they unconsciously breed a contempt for them, and, giving rein to that love of mysticism which is inherent in human nature, they ultimately put faith in the wonderful little pellets of Hahnemann, or in any other practice which does not appeal to their understanding, but promises the attraction of novelty.

The influence of the mental operations over the functions of the body is indeed powerful. It is often found not only to be the cause of various disorders, but it is also an instrument the physician can frequently use in promoting a cure. Patients will frequently exclaim against the use of certain remedies simply because they entertain erroneous notions concerning their effects, or are skeptical in regard to their remedial virtues. With such people a medicine with which they are wholly unacquainted, dispensed by the hand of the doctor, is far more efficacious than any prepared by the most skilful pharmacist according to written instruction.

And why is this the case? Simply because we appeal to the imagination. We have frequently witnessed the wonderful results attained through this influence, and no one will question our right or our ability to make use of this power in all cases where the welfare of our patient will be advanced thereby, without compromising the interests of morality. It is true that empiricism has owed its success to the advantage it has taken of this faculty

of the mind, and that our homœopathic neighbor appeals to it alone through the instrumentality of his saccharine pellets, his look of wisdom, and his minute questions about all manner of irrelevant things; yet these facts do not militate against the regular physician, who, with a proper regard for his own reputation and the credit of his profession, does not hesitate to make use of a lever so efficient in elevating the sick body to its standard of health.

A little mysticism is not altogether objectionable even to intelligent minds, and it cannot be denied that the Hahnemannian globule, in conjunction with a few hygienic regulations, has "acted like a charm" in dissipating troubles which a more active medication might have increased. The minuteness of a dose will often create the idea that it is one of great power, and this belief certainly aids the remedy in its operation; particularly so if the attention has been directed to the changes it is intended to produce.

In almost all cases of disease I think that the patient will progress most favorably when he possesses no knowledge of the medicine he is taking, but is thoroughly impressed with the idea that it will bring about certain results. In this way bread pills have induced salivation, an emetic has had the effect of a purgative, and a few drops of pure water have brought refreshing sleep to a suffering patient.

Medicines prepared by different chemists vary greatly in their strength, especially those known as fluid extracts and tinctures. Writers upon therapeutics seldom fail to warn their readers of this fact, and enjoin upon them the necessity for being upon their guard whenever using powerful medicines in either of these forms. It is a matter of great satisfaction to be assured of the strength and reliability of the remedies we employ, but this satisfaction can never be ours so long as we adhere to the custom of writing prescriptions which may be compounded at any one of the hundreds of drug-stores that flourish in our midst. By dispensing medicines purchased from chemists in whom we have confidence, we may always feel assured of the extent of their purity and strength.

Then the subject of *dosage* is one of importance. There has been a question in my mind when administering medicines in the form of pill or of powder as to whether I was securing any greater accuracy in the dose than when I ordered a mixture and depended upon the teaspoon or tablespoon method of measuring. If the substances we prescribe were always thoroughly disseminated through each other as well as through the vehicle which holds them, and if all apothecaries exercised the skill required to make a neat division of doses, then there would be no question about it. But we can never rely upon this being the case. As a rule, the fluid form is accepted as being the best and most convenient way of giving medicines; but spoons vary so much in size and shape that we can never be satisfied of their capacity until it is tested. In dispensing there is this advantage: by taking the spoon to be used, and with it measuring the vehicle which is to contain the remedy, we can secure perfect accuracy in the dose.

Perhaps one of the greatest inducements to recur to the old plan of dispensing may be found in the pecuniary benefits to be derived therefrom. An eminent physician, in speaking of the general practitioners of England, declared that they would ultimately raise themselves to be the almost exclusive medical practitioners of the land; "for low prices, with equal qualifications, will in the long run invariably carry the day." People may be embarrassed in determining the qualifications of their medical attendants, but they are never confronted with this difficulty in estimating the expenses. Herein lies the chief attractive point of the "homœopathic" practice. What can be more agreeable than to avoid taking the "nasty medicine," which is almost as expensive as the doctor's visits! For this reason alone there are many who will employ these charlatans while nature is working a cure, or until some alarming symptom induces them to drop the man of sugar and appeal to the wisdom of the "old school" doctor, whom they usually regard as their "sheet-anchor" in the hour of real trouble, but, like the sheet-anchor, he is only thought of when there is danger of a wreck. The druggist's bill is an item of no mean importance, particularly so to those in moderate circumstances, and we need not wonder that there exists a strong desire to escape a bill of this kind, which, in a case of tedious illness, is sometimes as large as that of the attending physician. It is said that a retired apothecary, upon being asked how he had made his fortune, promptly responded, "By selling aqua destillata." Now, aqua *Schuylkillensis*, though not so elegant, is in many instances quite as efficacious, and may be had for nothing. A few drops of aconite, nitre, or morphia disseminated through this vehicle will answer all the purposes of the same mixture put up in a bottle elaborately labelled, wrapped, and tied, and will be the means of saving time, trouble, and expense.

I do not wish to ignore the real value of those honorable and cultivated gentlemen who in the skilful and intelligent pursuit of their calling have made themselves ornaments to the pharmaceutical profession as well as invaluable aids to our own; but there is a class styled "pharmacists" whom we would gladly do without. These men are the vendors (and sometimes the factors) of every variety of patent medicine, agents for homœopathic "specifics," and almost anything else by which they may turn a penny. Many of them are in the habit of prescribing for the sick, the nature of whose ailments they know nothing about; and some months ago my attention was directed to one more enterprising than his fellows, who added to his already onerous duties the "labors" of an obstetrician. This new branch of the business, however, he was soon led to relinquish through the fright he received in a case attended with post-partum hemorrhage.

Dr. George B. Wood, in an address delivered before the College of Pharmacy, says of these irregular practices, "Do you suppose that medical men can with complacency behold their peculiar province invaded, their sources of livelihood cut off, the very bread taken from their mouths? Will they

not be compelled in self-defence to make resistance? and can resistance be made anywhere so effectually as on the ground of your adversary? It appears evident to me that were apothecaries to undertake the management of diseases, physicians would almost universally recur to the plan they have abandoned, and, like their brethren in other parts of the continent, would supply their own patients with medicines." I think it is our duty to discountenance in every way those who are at all open to this charge, and who make the art of pharmacy merely an *addendum* to what may be termed a "general notion" or commission business in articles having no relationship whatever to medicine.

Many will be surprised at the number of remedies in daily demand that are, or can be, used in a very concentrated form, also at the number of solid substances capable of being held in strong solution. Dr. Squibb, of New York, has invented a ready way of accurately dispensing powerful fluids by using a pipette with a capacity of from one to thirty minims. This little instrument is used by plunging it into the liquid in the vial up to the minim mark which indicates the desired quantity, then, closing the upper end with the fore-finger, the charge is transferred to the vessel in which the doses are to be mixed. Dr. Squibb also offers a list of forty-four articles of the active materia medica in their most potent and concentrated form.

Did space permit, I might dwell upon the easy manner in which this mechanical duty may be performed, and enumerate the many valuable remedies that may be prepared in such a way as to occupy but a very small space in the pocket-case, from which they can be dispensed with advantage to ourselves and patients.

1813 COLUMBIA AVE.

NOTES OF HOSPITAL PRACTICE.

EPISCOPAL HOSPITAL.

SERVICE OF LOUIS STARR, M.D.,

Acting Visiting Physician.

Reported by DR. B. J. RUDDEROW, Resident Physician.

CASE OF DIFFUSE PULMONARY GANGRENE FOLLOWING PNEUMONIA.

A. R., 43 years of age, a dyer by occupation, was admitted to the medical ward on July 31, 1875. He had a healthy family history, and, notwithstanding intemperate habits, enjoyed good health himself until 1866. After this time he suffered occasionally from intermittent fever, and had frequent attacks of diarrhœa during the summer months, but was never ill enough to be confined to bed. For the past six months he had been unusually strong and well, though he had made no change in his mode of living.

Early in July, however, he began to have diarrhœa; this, as it was of the same character as he had always had in warm weather, caused him no uneasiness, and he continued to work until the 26th, when he had a severe chill, followed by fever, pain at the base of the right lung, difficulty of breathing, and cough, attended with the expectoration of tenacious mucus. These symptoms continued until he was brought to the hospital, the only change being in the sputa, which became rusty and slightly fetid.

When admitted, he was very weak and much emaciated, having, he stated, lost flesh rapidly since the beginning of his sickness; his face was flushed, his skin hot and dry, and his pulse 120 per minute, weak and compressible; there was considerable pain in the right side of the chest, great difficulty of breathing, and frequent cough, with a free expectoration, the sputa being brownish-red in color, frothy, very offensive, and not at all tenacious; his tongue was heavily coated with a dark-yellow fur. There was almost complete anorexia, considerable thirst, and some tendency to diarrhoea.

On examination, the right side of the chest was found to be slightly bulging, and the intercostal depressions were less marked than on the left side. There was dullness on percussion, with diminished elasticity extending over the whole of the lower lobe; this was most marked posteriorly, in which position there were also bronchial breathing and a few subcrepitant râles. The left lung was normal. The abdomen was tympanitic. The superficial veins of the right side were distended, and on palpation the smooth edge of what appeared to be an enlarged liver could be distinctly felt, extending from two and a half to three inches below the margin of the ribs on the right side. Over this tumor the integuments were somewhat cedematous, and pitted slightly on pressure. There was no ascites. The heart-sounds were feeble, but no murmur could be detected. The urine contained a small quantity of albumen.

The patient was put upon supporting treatment, and a jacket-poultice was applied to his chest.

During the night of July 31 and the following day his condition remained about the same.

On August 2 he was very weak, and slightly delirious, tongue brown and dry, lips and teeth covered with sordes, pulse 120, respiration quick and labored, breath very offensive, cough constant, with free expectoration, sputa very fetid, dark brown in color, containing small tinder-like clots of blood. Physical exploration revealed flatness on percussion over the whole posterior aspect of the right chest, and from the third rib to the base laterally and anteriorly, while above this line the resonance was impaired. Alterations in position caused a moderate change in the level of the flatness on the anterior and lateral surfaces, though none on the posterior. Over the area of flatness the respiratory murmur was feeble and distant, and the vocal resonance and fremitus diminished. These signs were most marked posteriorly; when he was placed on his belly, however, the respiratory murmur was louder, the vocal resonance and fremitus more distinct, and numerous moist râles became audible. Loud bronchial râles, both dry and moist, could be heard on either side of the chest; they were more distinct on the left, where they were attended by a decided fremitus; in other respects the left lung seemed to be healthy. The heart-sounds were very weak.

At 3 P.M., about two hours after the above examination was made, he took advantage of the temporary absence of his attendant to get out of bed and walk to the water-closet, where he was found dead a few moments afterwards.

At the post-mortem examination, which was made five hours after death, rigor mortis was well marked. On opening the thorax, the middle and lower lobes of the right lung were observed to be bound to the walls of the chest by firm adhesions; the upper lobe was free, the pulmonary and costal pleuræ being separated by a layer of serous liquid, which, when carefully removed, measured one ounce. The upper lobe was congested; the lower and middle lobes were completely hepatized, and in the upper posterior portion of the former there was a large sac, about three inches in diameter, which contained nearly a pint of thick, greenish-black, excessively fetid fluid, mingled with shreds of broken-down

lung-tissue. The walls of this sac were formed by the thickened pulmonary pleura externally, and by the decomposing and cedematous lung-tissue internally. Incisions made in the hepatized portions of the lung gave exit to a thick, greenish-black ichor, having a very offensive and slightly alliaceous odor. The lung weighed six pounds. There was nothing abnormal in the left lung, except some congestion of the lower lobe.

The pericardium was healthy; the heart was normal in size, and there was no valvular lesion, but there was a large, firm, ante-mortem clot occupying the right ventricle and auricle and extending into the pulmonary artery.

When the abdominal cavity was laid open, the liver was found to reach three and a quarter inches below the right costal border. The organ was enlarged and fatty, and weighed six and a quarter pounds.

The kidneys were somewhat fatty.

The other abdominal organs were free from disease, and there was no fluid in the peritoneal cavity.

Remarks.—This case is interesting not only as an example of a rare condition,—viz., pneumonia culminating in diffuse gangrene,—but also from the fact that during the latter part of the attack the physical signs resembled those observed in pleurisy with effusion. The change in the line of flatness over the anterior and lateral surfaces of the chest when the position was altered can hardly be explained by alterations in the level of the small amount of fluid situated over the upper lobe. But, even supposing this to have been so, it could have had nothing whatever to do with the development of râles, the increased respiratory murmur, and augmented vocal resonance and fremitus noticed over the posterior portion of the lower lobe when the patient was placed on his face. Bearing in mind the post-mortem appearances, a more rational explanation seems to be that the fluid which was contained in the sac, as well as that which infiltrated the whole of the middle and lower lobes, was affected by gravity, and, being displaced by changes in the position of the body, allowed the small portions of these lobes still permeable to air to approach nearer the chest-wall.

TRANSLATIONS.

THE PRACTICAL VALUE OF THE ENDOSCOPE IN DISEASES OF THE URETHRA (Dr. J. Grünfeld: *Wiener Med. Presse*, No. 26, 1875).—In the treatment of chronic gonorrhœa when but small portions of the urethra are affected, the use of the endoscope is often of great assistance not only in carrying out the treatment but also in making an accurate diagnosis. If there is a well-marked infiltration, the diseased parts may be treated by the application of a diluted solution of iodine, applied by introducing a brush through the tube of the instrument. By this treatment the condition of the mucous membrane is much changed, and only a thickening remains, which can be benefited by cauterization with a finely-pointed crayon of nitrate of silver or sulphate of copper. This cauterization of the mucous membrane is said to give rise to but slight pain.

In other cases the gleet is due to a papillomatous growth of the mucous membrane, which, after its situation is accurately established, can be removed by means of forceps.

A case of this kind was treated by Dr. G. two years ago; numerous ones of a similar character have since been met with by him. The endoscope is also of value in the treatment of stricture the entrance to which cannot be found by the use of bougies of small calibre, for by its use the orifice can be discovered and a course of treatment instituted.

W. A.

A CASE OF FLOATING KIDNEY (*Bull. Gén. de Thérap.*, July 30, 1875).—M. G. Cabanellas reports the case of a man, æt. 36, who suffered from severe pain in the right lumbar region, where it was easy to discover a small rounded tumor, which was painful on pressure. He had had this trouble for many years. On consultation it was decided that the case was one of luxation of the right kidney without any organic disease.

The patient also suffered from obstinate constipation, so that he had an evacuation but once in five or six days, and then only by efforts which he compared to an *accouchement*. He was advised never to attempt to empty his bowels without having first taken a continuous injection of warm water, keeping it up for a half-hour or more. He followed this advice faithfully, and, as his constipation disappeared, the pain and swelling also vanished, and he regained excellent health.

J. W. W.

HEMORRHAGE IN A CASE OF EMPYEMA ARRESTED BY PLUGGING THE THORACIC CAVITY (*Bull. Gén. de Thérap.*, July 30, 1875).—In a case of empyema which was being treated by drainage, hemorrhage from the opening in the chest supervened, and resisted all the ordinary methods of treatment. In order to assure himself of the exact origin of the hemorrhage, M. Letiévant removed a large portion of the intercostal space, but, this opening being insufficient to permit of a complete examination of the pleural cavity, he resected four centimetres of the two ribs parallel to his first incision. He then plugged the thorax and succeeded in arresting the hemorrhage. The patient recovered. The reporter justly asks why he resected portions of two healthy ribs when the intercostal opening would have sufficed for the operation of plugging.

J. W. W.

THE CHANGES IN THE BRAIN IN CHOREA MINOR (Dr. Julius Elischer: *Virchow's Archiv*, lxiii. 1875).—From the examinations which he has made, Dr. Elischer concludes that the original causes of chorea cannot be referred to a single organ. The changes found in various organs which have been examined, including the peripheral nerve-trunks, spinal cord, and central ganglia of the brain, show that the advance of the disease is not confined to one locality. They show also that the pathological evidences by which it is characterized depend upon irritative processes. This latter view is sustained by the increase of the nuclei in the connective tissue of the peripheral nerve-trunks and along the vessels of the cord, and in one case, of which he made a most detailed examination, by the thickening and chalky deposits in the external tunic of the vessels of the thalami and corpora striata.

In these results of irritative processes retrograde metamorphosis takes place, and thus the results which attract the most attention in the blood-vessel system are reached. From all this he thinks that these changes (granting that they are really characteristic of chorea) result from an irritant, the influence of which is diffused over all the nervous system, but which acts more powerfully at some points than at others.

W. A.

ON AN ANOMALOUS CANAL FOR A DEEP TEMPORAL ARTERY SPRINGING FROM THE MIDDLE MENINGEAL ARTERY WITHIN THE SKULL (Dr. Gruber: *Virchow's Archiv*, B. lxiii. 1875).—Twenty-two years ago Dr. Gruber called attention to an anomaly of the origin of a deep temporal artery from the meningeal media during its course within the skull, and since that time he has been looking for it, but unsuccessfully. He has, however, found the canal several times in the temporal bones of macerated skulls. In an examination of about four thousand skulls the anomaly was met with twenty-five times: six times upon both sides, eight times upon the right, and eleven times upon the left

side. The object of the canal is to permit the escape from the skull of a deep temporal artery which originates from the middle meningeal, and after its escape from the bony canal becomes a supernumerary temporal artery.

W. A.

FRACTURE OF THE LARYNX.—Chailloux (*Thèse de Paris*, 1874) examines from a surgical-forensic standpoint those unusual cases of fracture of the larynx which are caused by strangling and hanging. The thesis, however, has nothing essentially new upon the subject, so that, although containing notes of various scattered cases, and, therefore, convenient for reference to those conversant only with French, it is inferior to the work of Gurlt on Fractures.—*Centralblatt f. Chirurgie*, No. 25, 1875.

X.

METHOD OF OPERATING IN ANAL FISTULA.—M. Jules Felix, of Brussels, employs a ligature of stout English silk, one end of which is passed through the fistula and back through the anal opening. The ligature is then moved backward and forward with a see-saw motion, cutting its way rapidly through the intervening tissues until a complete section is made, as with the *écraseur*, without the loss of a drop of blood.—*Le Mouvement Medical*, No. 28, 1875.

X.

THERAPEUTIC NOTES.

ANTI-CATARRHAL PILLS.—

℞ Gum. ammoniac., gr. xxx;
Ammonii carbonat., gr. xv;
Ipecac. pulv., gr. iii;
Morphiæ muriat., gr. iss;
Mucilaginis, q. s.—M.

Ft. in pil. no. x. Coat with balsam of tolu dissolved in chloroform. Take one pill morning and evening in chronic bronchitis.

DRESSING FOR ULCERS.—

℞ Olei cadini, ℥ss ad ℥i;
Pulv. calcii sulphat., ℥vj.—M.

To be thinly spread on dressings for ulcers, and renewed three, four, five, or six times daily, taking care to cleanse the ulcers after the dressing has been removed. Of especial value in the treatment of profuse and fetid suppuration.

TREATMENT OF LEAD-COLIC BY CHLOROFORM.—Chloroform has lately been used in lead-colic, both externally and internally (by inhalation), with advantage. Dr. Barduzzi has employed the following formula with success in one case which had resisted other forms of treatment.

℞ Chloroformi, ℥i;
Syr. acaciæ, ℥ii ℥vii;
Aq. destillat., aa ℥vj.—M.

This potion is administered in two parts, with a quarter of an hour interval.

In Dr. B.'s case this potion was given three times in thirty-six hours, with the effect of relieving the patient greatly.

Inunctions with a chloroform embrocation were at the same time employed on the abdomen.

IN SYPHILIS.—

℞ Hydrarg. bichlor., gr. i;
Opii, gr. ii;
Pulv. glycyrrhizæ,
Ext. gentian., aa ℥ss.—M.

Ft. in pil. no. 16. One to be taken morning and evening after eating.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, AUGUST 28, 1875.

EDITORIAL.

UTOPIA.

THERE can be no doubt at the present day that all individuals are not equally responsible for their offences against law or morality. Hereditary predisposition, the presence or absence of the "criminal neurosis," the influence of education and surroundings, are all powerful factors in the production or prevention of crime; and the time will come, we hope, when the circumstances determining these conditions shall have been so carefully studied and recorded as to permit of a natural and rational classification of criminals into various divisions, ranging from the thoroughly responsible to the totally irresponsible and insane. When this is done accurately and scientifically, when it shall be possible to distinguish with but little risk of error between the poor wretch who is blindly impelled to his deeds of lawlessness and outrage by an influence generated, perhaps, before he was conceived, and the cold-blooded, methodical villain, who, knowing the right, deliberately seeks the wrong, it will also be possible to apportion to each his proper meed of punishment, and restrain, confine, or execute with some regard to the relation which should obtain between the punitive measure and its object.

We can look forward then to the recognition by legislators of the fact that "moral and physical disease may have a common origin, and consequently common laws of cure," and to the elucidation by physicians of those complex organic processes which, according to Maudsley, render lunatics and

criminals "as much manufactured articles as are steam-engines and calico-printing machines." We can then hope to have framed not only retributive but also prophylactic and curative laws, and to see the medical expert a recognized authority in every tribunal of justice and a guide and counsellor in its judgments. We shall understand or abolish such apparent discrepancies as on the one hand the conviction and execution of a mere child for causeless and objectless murder, and on the other the exoneration on the ground of "insanity" of the "spiritual adviser" of a pious congregation from the undenied charges of indecent assault and attempt to commit rape. We shall know why lawyers, when they sin, peculate, why clergymen, of late years, fall victims to the temptations of the flesh,* and why physicians—never wander from the path of rectitude.

While waiting, however, for the accumulation and development of this knowledge, if we are evolutionists we can solace ourselves with the Spenserian belief that whereas "man's primitive circumstances required that he should sacrifice the welfare of other beings to his own, his present circumstances require that he should not do so." His powers of restraint and self-control, like his other faculties, increasing with use, it follows that "progressive morality is a necessary consequence of the evolution of life," and that, if no mental or moral cataclysm occur, time alone will bring about a condition of perfection.

"Roll swiftly round, ye wheels of Time,
And bring the blessed day."

LEADING ARTICLES.

THE INFLUENCE OF THE LOWER ORGANISMS IN THE PRODUCTION OF INFECTIOUS AND CONTAGIOUS DISEASES.

I.

MODERN, and especially recent, researches into the connection between infection and contagion, on the one hand, and the development of microscopic organisms, on the other, possess the deepest interest, not only for the pathologist but also for the practical physician. It is only by examination into the cause of disease-action that rational methods of prevention and cure can be fairly hoped for; and, although the work of the post-mortem room and the laboratory may seem to have but a remote bearing upon the clinical study of disease in many cases, yet it is by this in great measure that the physician of the future is to win his greatest triumphs.

* "When it was asked Ovid why Ægyptus became an adulterer, he made no answer but this: 'Because he was idle.'"—RABELAIS.

Accepting this view, it is not necessary to apologize for offering in the pages of a journal intended for the practical physician a review of recent progress in our knowledge of certain points connected with the etiology of the infectious and contagious diseases.

Before presenting the analysis of these investigations which it is proposed to give, it seems advisable to allude to the subject of contagion and infection in general, and also to give some account of the organisms themselves which are now so generally believed to play a part in the production of the zymotic affections.

Two hypotheses in relation to the origin of the infectious and contagious diseases may be regarded as at present dominant, to the exclusion of all others. The first of these regards the poisons of infectious diseases as *chemical processes*. "A burning shaving," says Liebermeister, in elucidating this subject,* "can set fire to a house and an entire city. The chemical process of burning multiplies itself ad infinitum, so long as combustible material and oxygen are present under favoring circumstances."

The second hypothesis ascribes the disease-process to the *multiplication of living organisms*.

Among chemical actions it is chiefly the processes of fermentation and decomposition which, by their capacity for extension by means of the smallest quantity of matter, show the most striking analogy to the contagious diseases. The name "zymotic" diseases (from *ζυμων*, to ferment), so generally adopted some years ago for this class of affections, shows the notion prevalent of their nature. "But the only ferment processes which can be taken into consideration are all associated with the presence and multiplication of low organisms. Accordingly, the existence of disease-poisons which have the capacity for infinite extension necessarily gives rise to the theory of a *contagium vivum*, and the conclusion can only escape those who satisfy themselves with the simple facts, and do not care to build up any theoretical idea on the origin of the diseases in question" (Liebermeister, *loc. cit.*).

It is certainly a fact that the hypothesis of living organisms as the origin of infectious disease has a high degree of plausibility to begin with, and though the evidence in its favor may be as yet comparatively meagre, conflicting in some details, and in many respects contradictory, yet it is constantly increasing by the labors of a host of conscientious and able workers; and the hypothesis itself bids fair to explain much in the action of disease which has hitherto been wrapped in obscurity.

The organisms to which are attributed the causation of disease belong to the lowest class of the vegetable kingdom. So minute are they, so little do they offer in the way of organization, and such formidable difficulties attend their investigation, that it is not surprising that their very nature, whether animal or vegetable, should long have been a matter of dispute.

Even at present, the whole subject of these lower organisms is beset with difficulties; not only their mode of action, but even their botanical nature and classification, continues to be the subject of active controversy.

Want of space, and the desire to avoid clogging with confusing detail an article intended rather for the general medical reader than for the specialist, prevent us going deeply into the subject of the classification and arrangement of the various organisms believed to be concerned in the origin and propagation of disease. Fortunately, we have at hand a very excellent article by Dr. L. A. Stimson, of New York,† from which we shall abstract such portions as seem necessary to elucidate our subject, and to which we can with pleasure refer any one desiring a clear and succinct *résumé* of the various names and classifications of the organisms under consideration which are at present in use, or which have been proposed.

The organisms of which we have been speaking are those commonly known under the general designation of bacteria or vibriones.

The terms *bacterium* and *vibrio* are well known, though their use is not infrequently coupled with a very imperfect idea of the organisms themselves. Briefly, it may be said that the term bacteria is, in France and Germany, ordinarily associated with microscopical bodies, round, oval, or rod-like, and jointed, found especially in putrefying vegetable and animal infusions. In England these organisms were formerly called vibriones, but this term is giving way to that of bacteria.

Used in a narrower sense, bacteria denotes stiff, rod-like bodies, single or jointed, motionless or endowed with an oscillating movement in place, while vibrio is applied to those that have an undulating, sinuous motion and move rapidly across the field of the microscope. These organisms are now almost universally believed to be of vegetable origin.

It would be impossible to give here an account of the various classifications proposed and adopted by different writers, but we shall endeavor to give some idea of those now most generally in use, in order that the terms used may be more intelligible. We extract from Dr. Stimson's article the classifications of Cohn and Billroth. Cohn, he says, makes the following divisions:

"BACTERIA.—Tribus I., *Spharobacteria* (Ball bacteria): Variety 1, Micrococcus.

"Tribus II., *Microbacteria* (Rod bacteria): Variety 2, Bacterium, subdivided into B. termo and B. lineola.

"Tribus III., *Desmobacteria* (Thread bacteria): Variety 3, Bacillus; Variety 4, Vibrio.

"Tribus IV., *Spirobacteria* (Spiral bacteria): Variety 5, Spirillum (of Ehrenberg); Variety 6, Spirochæte (of Ehrenberg).

"Billroth makes no claim to a complete botanical classification. He deals principally with the forms which

* Ziemssen's Cyclopedia of the Practice of Medicine, Am. ed., vol. i. p. 20.

† Bacteria and their Influence upon the Origin and Development of Septic Complications of Wounds.—New York Medical Journal, August, 1875.

are found in animal infusions, and in the body during disease or after death. But, while he does not attempt to describe all the varieties, he gives a complete history of those which he has observed, tracing the whole cycle of their development, and showing so close a genetic relationship between them that it seems probable future investigation will show the others to be included in it. He considers all the forms combinations of spherical and cylindrical bodies, representing only different periods of development. His nomenclature and classification being based upon this opinion, he groups all under the name *coccobacteria* (κόκκος, a berry, and *βακτηρία*, a little rod), and gives to the different forms names which are compounds of these two with words denoting the number, size, and arrangement of the component parts; micro-, meso-, and mega-, signifying small, medium, and large; mono- and diplo-, single and double; strepto-, in chains; glia- (*γλία*, glue), in groups; asco-, in bags; and petalo-, in plates. This classification is simple and clear, for each name has the great advantage of describing accurately the form to which it is applied."

There are two terms met with constantly in recent pathological works which are not included here; these are *bacteridia* and *micrococcus* or *microzyma*. The former was applied by Davaine to long immovable forms of bacteria found by him in the blood of animals affected with anthrax; they belong in variety 3, bacillus of Cohn, while the latter is applied to the innumerable round or oval forms found in the tissues, secretions, or blood of persons suffering from septic diseases, and in putrefying liquids.

Bacteria are cells lacking chlorophyl, of spherical, oblong, or cylindrical form, which multiply by scission and vegetate either simply or in groups. Billroth and Cohn maintain that there is no genetic relationship between bacteria and any of the yeast-plants. Billroth, indeed, says that whenever any luxuriant yeast vegetation except *oidium lactis* is growing rapidly, the elements of coccobacteria do not flourish.

The germinative spores of bacteria, first described by Billroth under the name *dauersporen*, are glistening dark-bordered globules, which develop in their interior masses of coccus, which are set free by the bursting of the envelope, but are retained in contact with it sometimes by the presence of a mucous or gelatinous substance called *glia*. The coccus may multiply by lengthening and scission, or they may lengthen into bacteria, and gradually free themselves from the enveloping glia by their own active motions. This division or scission ordinarily occurs in one direction only (when it takes place at right angles also the well-known sarcinia forms are the result); the two pieces are held together by the glia, and each divides again and again. In this way rosary or chain-like forms result, the "streptococcus" of authors. The bacteria may often lengthen and divide transversely, forming the well-known jointed bacteria. All these developments, Dr. Stimson says, may be observed by any microscopist, and he has himself followed them frequently. The division or scission

may take place so rapidly that each bacterium forms a streptococcus, and the result is a gelatinous mass filled with coccus, and forming what is known as zoogloea. If the glia is very tenacious it may form a sort of membrane about the mass, known as ascococcus (*ασκός*, a bag), which sometimes shows amœboid movements. After a time this membrane bursts, the coccus escape, and the empty husk is found at the bottom of the vessel.

The final fate of bacteria may be either to leave the enclosing husk as finely granular sterile mucus, to break up rapidly into micrococcus within the husk, expanding it considerably, and forming a variety of ascococcus, or to contract into one or more glistening, dark-outlined bodies which are the germinative spores (*dauersporen*) above alluded to, and which, after a certain period of repose, may again germinate. The vitality of the latter is not destroyed by freezing, boiling-heat, or by drying, and these spores carried about in the air are undoubtedly the principal agents in the production of coccobacteria. Billroth had some which germinated after having been kept eight years. This is the only form which withstands drying; the coccus and bacteria do not.

The isolated coccus possess only a motion which cannot be distinguished from the ordinary molecular movement of very small, inert portions of matter, the so-called Brownian movement. When, however, they remain united in chains (streptococcus) they appear to have a sinuous serpent-like movement, which carries them sometimes with great rapidity across the field of the microscope. Progression is made in either direction, and the large spiral ones often move forward and backward across the field with almost the regularity of a pendulum. Occasionally one end remains attached to a larger object while the other vibrates slowly to and fro, or the whole revolves rapidly about its long axis without change of place. The larger microbacteria chains are usually motionless, and the isolated bacteria show only an oscillatory motion without change of place. The motions seem to be dependent upon the fluidity of the medium and the presence of oxygen.

For their nourishment bacteria need carbon, nitrogen, and certain of the elements of the ashes of ordinary yeast. Bacteria resemble green plants in this, that they assimilate the nitrogen contained in their cells in the form of ammonia compounds, which animals cannot do; on the other hand they differ from green plants and resemble animals in this, that they cannot take carbon from carbonic acid, but only from the organic compounds of carbon, especially the hydrocarbons and their derivatives.

Bacteria are not parasites; they do not live upon the materials intended for the nourishment of the tissues in which they are found, and cause the death of these tissues by starvation, but they probably live upon some of the elements of the substance itself, by the withdrawal of which new chemical combinations of the others are caused. Putrefaction is a correlative phenomenon of life, because it occurs only when a microscopical vege-

table organism nourishes itself and multiplies at the expense of a part of the putrescible substance. This organism is the bacterium, at least in some of its forms or varieties. Billroth believes its form known as *B. termo* to be the only one which excites putridity. Cohn says that they multiply as long as putridity lasts, and disappear so soon as it ceases. He is convinced that *B. termo* is the ferment of putrefaction, as yeast is the ferment of alcoholic fermentation, and that no putrefaction can begin without it or progress without its multiplication.

Bacteria exist in one form or another in all water, most animal tissues, and in the air. In the latter they are found only in the form of germinative spores, the other forms not being able to support the absence of moisture. Their presence in the healthy living body has been recently demonstrated beyond cavil by Billroth and Tiegel.

The spores which float in the air or are deposited upon exposed surfaces remain inert and innocuous until the conditions necessary to their development are supplied, among which moisture is the chief. It is generally agreed that these spores stand very low degrees of temperature (even 0° Fahr.) without losing their vitality. As regards the higher temperatures, observers differ, Cohn maintaining that a temperature of 140° Fahr. is sufficient to kill the spores, while Billroth, on the other hand, says they can stand 212° Fahr.

To recapitulate: Bacteria are microscopical vegetable organisms of two main varieties: 1. Round or oval cells 0.0005–0.0010 mm. in diameter, single or arranged in lines or groups (sphaerobacteria, micrococcus, Cohn; micrococcus, streptococcus, Billroth). 2. Cylindrical cells 0.002–0.003 mm. long, single, or arranged in lines (bacteria of both authors). There is no genetic relationship between them and ordinary mould or fungus. They are found in the air, water, and most animal and vegetable tissues. They are saprophytes,* not parasites, and are unable in themselves to cause any of the infectious diseases.

Having thus briefly sketched the current theories of contagion and infection, and having endeavored to give such an account of the organisms believed to be connected with disease-processes as to convey an intelligible idea of their general nature, we are prepared to examine the results of investigation as regards the influence of these organisms upon the production of the various infectious and contagious diseases. This examination, however, must be postponed to a future number of this journal.

SYPHILIS (*Archives of Dermatology*, July, 1875).—Stefanini reports the case of a young girl, who, having severe ulceration of the throat and velum, and iridocyclitis, which were unsuccessfully treated by the usual means, was rapidly cured by the injection of half a grain of calomel suspended in glycerin. Though no history of syphilis was obtainable, the author thinks the results of treatment warrant the diagnosis of that disease.

* Saprophyte, *σάπρως*, putrid, and *φύτον*, plant.

CORRESPONDENCE.

WASHINGTON, August, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES: SOME two years ago a prominent druggist of this city called my attention to the "Damiana" plant, claiming for it powerful aphrodisiacal properties. From his testimony and other certified evidence, I was tempted to give it a trial in that class of diseases generally termed "female weakness." My experience in these cases was quite satisfactory. In my hands it seemed to possess decided tonic properties, and when administered in combination with some of the ferruginous compounds, either the iodide or citrate, —giving of the "damiana" ʒij at a dose,—its beneficial effects were speedy and decided. With regard to its aphrodisiac virtues, my experience is as follows:

Case I.—In the early part of May last I was applied to by a negro woman aged 24, married four years. Three years before, she had been troubled with some uterine difficulty, the result of which was entire suppression of the menses; never had seen anything since. Her belief was that she had been "conjured" by some influence. She had never been pregnant, which was a source of unhappiness to both herself and husband. Her general health was good, save a slight leucorrhœa and pain periodically in the top of the head. I prescribed a general tonic and the "damiana" in ʒij doses three times a day. Three months later her husband called at my office (they lived some forty miles in the country) to report progress; said his wife had "done had her sickness twice, and got all the 'signs' of being in that way," and her leucorrhœa had also disappeared.

Case II.—A young man aged 32 had lost his virility through excess and dissipation; all sexual desire entirely wanting; had been in that condition for some eight months. Came to me for treatment about the 12th of June last. I gave the ext. (fld.) damiana in ʒij doses three times a day; in about two weeks he reported decided improvement; continued treatment for about two months, and then he reported his manly functions entirely restored.

E. A. DUNCAN, M.D.

PROCEEDINGS OF SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

JUNE 2, 1875.

Case of encysted dropsy of the peritoneum, in which suppuration had occurred and abdominal section was performed, with recovery.

DR. J. EWING MEARS read a paper describing the case of a lady, æt. 40, who had had six children, the youngest being 7 years of age. She dated the beginning of her illness from the last confinement, in which she was informed that the placenta was adherent, and she suffered severely from post-partum hemorrhage.

About three months after confinement, she noticed a small swelling in the right inguinal region; it was

freely movable, so that it could be pushed about by the finger. For the period of one year the swelling remained quiescent, then it began to enlarge until it attained the size of a large goose-egg.

On making an examination, Dr. Mears found the patient much emaciated and debilitated. The heart's action was feeble and intermittent. Orthopnoea was present. The expression of the face was haggard, and betokened much suffering. The pain was constant and of the most exhausting character; the patient expressed herself as suffering from a "great burden." There was no œdema. The abdomen was enlarged to the size of a full-term pregnancy. The surface was smooth and regular, and the veins were not enlarged. The abdominal walls were not very tense, but they could not be lifted from the tumor. On percussion, resonance was elicited over the entire surface as far below as the line of the umbilicus; below this line dulness was marked on both sides, especially on the right. Fluctuation was not very distinct, but still was perceptible, giving evidence of imprisoned fluid. Change of position did not affect the percussion-sounds.

A vaginal examination showed that the uterus was in a condition of marked anteversion and fixed in its position. Pressure applied to the tumor through the abdominal walls did not move the uterus. Owing to its fixed position, it was impossible to introduce the sound to a greater depth than one inch. The finger in the vagina could detect a tumor in the pelvic cavity.

The diagnosis could not be made exactly, but an operation of exploration was advised and was consented to, and performed as follows. The abdominal cavity was opened by making an incision two inches in length in the linea alba, midway between the umbilicus and the pubes. On introducing the finger, he found adhesions between the tumor and the parietes of the abdomen, which were separated with some difficulty. He enlarged the incision to four inches, in order to obtain a more extended view of the tumor. Through this opening he introduced his hand and separated the parietal adhesions, which were general. On making an examination after the separation, he found that the anterior wall of the tumor was in great part above, formed by the great omentum, covered by a dense layer of lymph, and firmly adherent to the subjacent intestines; its lower edge was rounded and was fastened to the intestines below, forming a smooth junction with them. Below the border of the omentum the intestines were firmly adherent, and formed the remaining portion of the anterior wall.

Seeking for the line of attachment between the intestines, he made an opening with his finger, and gave exit in this way to over two gallons of fibrinous pus. The adhesions between the intestines were freely broken up, and free exit thus given to the contents. Owing to the very firm adhesions between the thickened omentum and the intestines which lay beneath, it was found impossible to separate them. The effort made to accomplish this detached at one point the peritoneal layer of the bowel. The omentum was extremely vascular, and free hemorrhage occurred on section of it. At one point Monsel's solution and the hot iron failed to control the bleeding, which yielded finally to the application of a carbolized silk ligature, the ends of which were cut off close, when the ligatured portion was returned to the cavity of the abdomen. The parietal peritoneum could not be recognized as such, the entire inner surface of the abdominal wall being covered by a layer of lymph, measuring at least one-third of an inch in thickness.

The intestines were fastened together by dense bands of lymph, and their surfaces were also covered by dense layers. On making a section of the omentum, the normal fat tissue was found surrounded by layers of lymph one-half of an inch in thickness.

The abdominal cavity was cleansed by soft sponges, and the wound closed by five iron-wire sutures, an opening being left at the lower part for the purpose of drainage. The dressing was completed by the application of a compress of cotton-wool and bandage, and the patient was placed in bed, and one-third of a grain of morphia given hypodermically. The pulse was 96, and feeble; the skin was cool; vomiting occurred. Towards evening, reaction was fully established, the pulse rising to 118 and the skin becoming hot. The catheter was employed to relieve the bladder, the color and quantity of the urine being normal. A diet of barley-water was ordered. Morphia in one-third-grain doses was given hypodermically as required.

The after-treatment consisted chiefly in supporting measures, the administration of quinia and iron, and careful attention to the wound and syringing out the cavity with a weak solution of carbolic acid.

When the character of the cyst is considered, the difficulties of the diagnosis in this case can be fully appreciated. The history distinctly pointed to the existence of a tumor originating in the right inguinal region, at first quite small and freely movable under the finger. The physical signs showed unmistakably the presence of a tumor containing fluid. The absence of resonance on percussion was caused by the thickened overlying omentum, and the thick purulent fluid in the cyst gave rise to quite well-marked fluctuation. Inferiorly, the walls of the cyst were so thickened by plastic deposits as to prevent the determination of its true nature by vaginal examination. The decline in the health of the patient during the last year might have been accounted for by suppuration in an ovarian cyst. It was no doubt caused by suppuration in the false cyst.

The question as to the proper treatment to be adopted in these cases is one of importance. The question relates rather to the method in which the proper treatment should be carried out, as it is impossible to conceive of any treatment leading to a successful result other than that which should promptly give exit to the purulent fluid and prevent its accumulation. This may be accomplished by tapping, or by incision, as practised in this case. In those forms of encysted dropsy in which the fluid lies in front of the intestines, evacuation with the trocar can be obtained without danger. Where the cyst lies behind the intestines, tapping through the abdominal walls would involve the great danger of puncturing the intestines which compose in part the walls of the cyst.

After the reading of the preceding paper, Dr. WILLIAM PEPPER said,—

Cases which may strictly be called encysted dropsy of the abdomen, though rare, are occasionally met with, either as a result of localized subacute peritonitis, or from the pseudo-cystic transformation undergone by large intra-peritoneal clots of blood. In such cases the seat of the fluid collection varies much. It may be within the fold of the great omentum, or in any segment of the abdominal cavity, being bounded partly by the surface of the adjacent viscera, and partly by the new-formed wall of lymph or fibrin. In several of the cases which he has observed, the cause of the attack has been a traumatic one.

ANEURISM OF THE INNOMINATE (*The Lancet*, July 31, 1875).—Mr. Frederick Ensor reports a case of innominate aneurism, in which he ligated the left common carotid at its bifurcation, the patient surviving for sixty-five days. He believes that chronic alcoholism and syphilis are the two most important causes in bringing about that condition of the artery which results in aneurism.

GLEANINGS FROM OUR EXCHANGES.

COMMON COLDS (*The Practitioner*, July, 1875).—Dr. J. Milner Fothergill briefly considers the causes and the treatment of common colds. Whenever and wherever they are met, they are the consequence of a chill, either to the general surface or to a portion of it. Ordinarily the body temperature is maintained by the equilibrium existing between the internal heat-producing area and the external heat-losing area, or the surface. When excessive heat-loss is not met by increased heat-production, a chill or lowering of the body temperature is the consequence; or if heat-production has been great, the cutaneous vessels are dilated, and if the surface be suddenly exposed to cold these dilated vessels are apt to be paralyzed instead of incited to contraction, and then heat is rapidly lost from the mass of warm blood in the cutaneous vessels. The catching cold or the escape from doing so depends upon the state of the vessels of the surface and their capacity to contract or the opposite. Consequently we can see that catching cold or escaping from it under apparently identical circumstances depends upon a condition far removed from either vision or sensation. Where heat-loss is met by heat-production at the time, no unpleasant consequences result; but where the heat-regulating processes are delayed, the loss of heat and fall of temperature at the time are followed by an excessive heat-production, constituting a pyretic condition which in its simplest form is a cold.

Obviously, the indications for treatment are to restore the balance between the heat-producing and heat-losing areas; and in order to do so we resort to such measures as shall increase the amount of blood in the outer area, and so diminish the amount in the internal area; that is, to increase heat-loss and lessen heat-production. We consequently use hot fluids, nauseant diaphoretics, warm beds, opium, and quinine, the latter usually after the action of the skin has been re-established.

DIET OF INFANTS AFFECTED WITH ACUTE INTES-TINAL CATARRH (*The Boston Medical and Surgical Journal*, August 12, 1875).—Dr. R. Demme, after an extended experience, recommends as the most appropriate food for infants affected with gastric or intestinal catarrh the following diet: Add from a quarter of a pound to a pound of beef, freed of fat, to two quarts of cold water, and let this stand from half an hour to an hour; then boil down to one pint; after cooling, skim off fat from the top, and filter. At each time of using (every two or three hours) without being warmed, this is to be mixed with freshly-prepared rice- or barley-water. In the intervals of meals the latter should be given alone, best without sugar, to relieve the thirst. If this food is refused, he gives a drink made with the white of an egg, using according to age from one to three eggs in half a pint to a pint of water which has been previously boiled and cooled down to 98°. If the child's strength begins to fail, brandy in doses of from five to thirty drops is added to the rice- or barley-water, from three to five times a day. With older children a mixture of milk with the rice-water or barley-water may be tried.

A PATHOGNOMONIC SIGN OF THE MORIBUND CON-DITION (*The Practitioner*, July, 1875).—Dr. John Shradly maintains that the earliest and therefore the most valuable symptom of approaching death is the up-and-down movement of the trachea; that the inferior laryngeal nerve, owing to a partial paralysis or impairment of its function, is concerned in the production of this phenomenon, and sounds the first note of alarm that the medulla oblongata is invaded. This tracheal symptom is particularly prominent in fatal cases of uræmic

convulsions, opium-poisoning, apoplexy, and delirium tremens; the air then ceases to stimulate the glottis, the respiratory movements are impaired, and the lungs can no longer decarbonize the blood. In pneumonia, Dr. Shradly thinks this symptom is of special value, anticipating, as it does, alarming changes in pulse and temperature, whilst in phthisis he has known it to be a precursor of death three weeks in advance. Its presence or absence in membranous croup should, in his opinion, be an important element in the prognosis of a given case of tracheotomy.

TREATMENT OF CHOLERA (*The Practitioner*, July, 1875).—Surgeon A. R. Hall, presuming the morbid state against which we have to contend in the collapse of cholera to be one of asphyxia caused by spasms of involuntary muscular fibres, due to a condition of hyperactivity of the sympathetic nervous system, asserts that the logical inference distinctly points to the exhibition of a remedy calculated to neutralize this condition. Such remedies are to be found in a class of agents which directly depress the activity of the muscular fibres of the circulatory apparatus. As medicines given by the mouth are generally immediately rejected, hypodermic injection is the best method of administering the drug used, which should be a pure sedative, chloral hydrate being the most efficient. It should be given in a solution of the strength of one part of the chloral to ten of water. Mr. Hall mentions nineteen cases treated on this plan by an Indian surgeon, seventeen of which recovered.

CONDITION OF THE BLOOD-VESSELS IN THE BRAIN OF THE INSANE (*The Dublin Journal of Medical Science*, June, 1875).—Dr. Atkins, having reviewed the morbid changes found in the cerebral vessels of the insane, portrays as follows the clinical effects which accompany and are caused by these changes. Starting with the condition of dilatation, we can at once see that, should active arterial hyperæmia be the initial cause, over-nutrition of the brain-cells will take place, exaltation of function will follow, the ideas will flow free and fast, fancy will be excited, imagination aroused, motor impulses become uncontrolled, and acute mania will be the result. Should this active hyperæmia change to passive congestion and stasis occur, a lowering of nutrition takes place, depression follows exaltation, the ideas become slow and shallow, indifference succeeds excitement, emotion becomes impeded and sluggish, and secondary dementia gradually supervenes. Should stasis persist, organic changes in the cell-elements ensue, blocking up of the outlets for waste products follows, resulting in the infiltration of these products into the tissues, apathy succeeds indifference, consciousness and volition are gradually abolished, the calls of nature neglected, and the unfortunate sufferer sinks into a state of hopeless fatuity. Years may elapse between these different stages, or the progress may be in the reverse direction,—towards health and recovery.

SLEEPLESSNESS (*The Lancet*, July 31, 1875).—Dr. George Johnson, in a lecture on the effects of overwork and mental anxiety, alludes to the sleeplessness and anorexia which are almost invariably caused by these conditions. He says it is not always easy to determine whether the loss of appetite is a direct result of the nervous excitement, or whether the restlessness is a result of the diminished supply of nutriment to the brain; but that it is probable that the two conditions have a mutual influence upon each other. In cases resulting from overwork, he has observed in numberless instances that a man who has been more or less restless for many months, and who, during that time, has had a loathing for food, after taking a grain of opium at bedtime for a few nights sleeps soundly for several

hours, and then wakes with an appetite. This tends to prove that in such cases the derangements of the nervous system are first in order of time and importance.

In cases of delirium tremens, the reverse is true; the delirium, wakefulness, and other evidences of nervous disorder are directly due to malnutrition of the brain, and, in spite of all treatment by drugs, will continue until a certain amount of nutriment has been absorbed. In these cases the substitution of narcotics for food has often been attended with rapidly fatal results. We see, then, that in delirium *a potu*, sleep follows and is favored by taking food; in cases previously nervous, the soporific effect of opium or chloral procures sleep, and then restores the appetite and assists digestion.

EXTIRPATION OF A TUMOR OF THE BLADDER (*Boston Medical and Surgical Journal*, July 8, 1875).—Dr. Carl Gussenbauer reports the case of a boy, æt. 12, who was supposed to have a vesical calculus, but who was discovered by Prof. Billroth to have a tumor of the bladder, and was operated upon by him in the following manner. After the patient was narcotized, the lateral incision for removal of stone was made. The finger introduced into the bladder showed immediately that a tumor nearly the size of the fist, with an uneven surface, projected from the posterior wall and extended towards the top of the cavity of the bladder. Owing to its size, it was found impossible to extract the tumor, with the finger, from the perineum. A supra-pubic incision was then made, without injury to the peritoneum, and to give sufficient room both recti muscles were cut across at their insertion; also a transverse incision into the bladder was made. Prof. Billroth soon came to the conclusion, after examining with the finger, that the use of the *écraseur* was not practicable or desirable, as the tumor possibly might be already adherent to the peritoneum, in which case the latter would have been so injured as to delay healing. He therefore decided to tear the tumor with his finger near its base, and to cut out the remainder from the wall of the bladder, after passing a ligature round to check bleeding. The extraction of the torn pieces of the tumor was not so easy, in spite of the large size of the incision, as would have been supposed. In dissecting out the pedicle it was necessary to turn the bladder partly inside out. It then appeared that the tumor took its origin from the muscular coat of the bladder, but had not attacked the outer coat or the peritoneum. The plan was, in case the peritoneum had been opened, to close the hole with sutures. Two arteries were tied, and the ligatures brought out through the upper incision in the bladder. The wound in the bladder was not closed, but a drainage-tube was drawn through the bladder, and brought out at the incision in the perineum. There was no subsequent difficulty, and in one month the patient was discharged, perfectly well. The tumor was found to be a well-marked, mixed tumor, principally a myo-sarcoma, but in places a myo-carcinoma.

PERIODICAL MELANCHOLIA (*The Medical Record*, August 14, 1875).—Dr. William Suflet, after careful study of numerous cases, has observed that, although repeated attacks of melancholia in the same person are not unusual, yet they are generally very few and very far apart, and if the patient does not entirely recover he passes into a permanent state of melancholia, or into some other form of insanity.

Loss of flesh invariably accompanied the attacks, and an increase in weight always followed as soon as they were over.

The attack always commences with a subacute anæmia. The general anæmia continues during the entire attack, and disappears during the interval. The skin and the mucous membranes are pale; the pulse is small and feeble; the veins, on the contrary, dilated and dis-

tended with blood. These phenomena are also quite constant and admit of no exception.

As regards the treatment of the disease itself, it is necessary to bear in mind that the psychical organ in this state is unable to produce any but painful sensations, and therefore all kinds of excitation, all impressions, even pleasant ones, have to be avoided, and the patient must be advised to keep quiet bodily and mentally. A few days' rest in bed is sometimes the most beneficial remedy. Exercise, travelling, admonition, and religious consolations only aggravate the psychical hyperæsthesia. On the contrary, everything that produces relaxation of the vaso-motor spasm, and congestion to the brain, acts beneficially. Thus, prolonged tepid baths, and, above all, opiates, though only palliatives, often make life endurable, especially in the variety of melancholia with great præcordial distress.

Other remedies which act similarly may also be tried, like inhalations of ether, chloroform, nitrite of amyl, chloral, etc.

CURE OF CYSTITIS BY DILATATION OF THE NECK OF THE BLADDER (*The Medical Record*, August 14, 1875).

—Dr. Howe reports the case of a woman, æt. 35, who had for more than a year been afflicted with a chronic cystitis for which various remedies had been tried without avail. It was decided to try the effect of dilating the neck of the bladder, in order to give the organ a rest and to examine the inflamed membrane. She was placed under ether, and the urethra gradually dilated with Molesworth's dilator until it was large enough to admit a finger. The bladder was thoroughly washed out, and she was then placed in bed and given quinia in tonic doses.

She complained of soreness about the urethra, and the urine dribbled from the bladder until the fifth day after the operation, when the sphincter muscle again resumed control. From that time on, micturition was performed in a natural manner, without pain or uneasiness, and she has entirely recovered.

SYPHILIS (*The Doctor*, August 1, 1875).—Mr. Henry Lee, in a recent lecture, expressed his belief that the product of primary syphilis is inoculable artificially, so as to produce the same effects as when it was naturally acquired; that the results of secondary manifestations are inoculable, so as to produce the same results; that the secretions from mucous membranes in syphilitic patients are very often the means of communicating the disease, and may sometimes be artificially inoculated.

As to treatment, Mr. Lee said that at whatever period of the disease we find the specific adhesive form of action, whether as a primary indurated sore, or an affection of the inguinal glands, or as papular, tubercular, or scaly eruptions, he held mercury to be indicated. On the other hand, when the disease, whether primary, secondary, or tertiary, has a tendency to produce suppuration, the use of this drug requires great caution; and the same may be said where the affected parts run rapidly into ulceration, although in some of these one form of mercurial treatment is wonderfully efficacious. He pronounced mercury to be injurious where mortification takes place, whether affecting minute or larger portions of the tissues.

TRISMUS NASCENTIUM (*The Richmond and Louisville Medical Journal*, July, 1875).—Dr. Philip A. Wilhite reports fourteen cases of trismus nascentium and of trismus, which he distinguishes as the acute and the chronic forms of the disease. The first symptom of trismus is inability to suck. This is pathognomonic of the disease. The child loses the power of seizing the nipple; and if the nipple should be forced between the jaws, it has no power of suction. The child seems to

be indescribably distressed, moans, whines, cries, is colicky, sometimes has griping passages from the bowels, is restless, uneasy, sleeps badly, has borborygmus, slight spasm of one or both upper extremities, then tonic rigidity of the whole muscular system with clonic spasms, which come on at intervals, and are often excited by touch or a noise. The expression of countenance is very peculiar, and can never be forgotten when once seen. The acute form terminates fatally in two or three days, sometimes in less time; while the chronic or milder form of the disease may continue for weeks and even for months—the child slowly wasting away to a mere skeleton, and dying of what was formerly called marasmus, which is but another name for gradual starvation.

Dr. J. Marion Sims many years ago contended that this disease was not traumatic tetanus, but was caused by pressure, generally the result of an inward displacement of the occipital bone, which always existed at birth, was kept up by the dorsal decubitus, whether in the cradle or the mother's lap, and which could be removed together with the symptoms of trismus simply by adopting the lateral decubitus. Dr. Wilhite cured seven of his cases by position alone, the other seven dying without treatment. He concludes that these cases justify the conclusion that trismus nascentium is the result of mechanical causes; the predisposing causes being protracted or tedious labor, and a too well ossified state of the fetal cranial bones. The exciting cause is undue pressure on these bones, more especially the occipital; while the immediate cause is undue compression of the medulla oblongata and the nerves originating from it. The cases given are all of one general character, and all go to show that the disease is the result of pressure exerted at the base of the brain. In all of them the pressure was produced by an inward depression of the occiput, differing, however, in degree from the slightest to the greatest possible.

INTESTINAL OBSTRUCTION (*Atlanta Medical and Surgical Journal*, August, 1875).—Dr. A. B. Copeland reports a case of persistent intestinal obstruction relieved by placing the patient in an inclined position, administering large distensile enemata of warm water, and finally by injecting tartaric acid and bicarbonate of sodium and following them immediately with an injection of water.

MISCELLANY.

WE publish the following epistle as a literary curiosity, and as a specimen of some of the trials undergone by the disciples of Æsculapius. It was recently received by a respectable physician residing at Cape May, who had been called in by a lady to attend her daughter-in-law during an illness of a serious nature. He paid about twenty visits, and sent in a bill for fifty dollars. Although the family was moderately wealthy, he was met with a request to reduce the amount to thirty-five dollars, which he very properly refused to do, and subsequently placed the matter in the hands of a lawyer. The result was the receipt of the money and of the subjoined vituperative communication from the husband of his patient:

"DR. ——:

"It is well for your mummied bones that you are securely out of my reach. . . . Were it not that I wish

to spare mother's old age from worry and trouble, I would let you whistle for your money. It is an outrageous extortion, at any rate; but as you will have been paid ere this arrives, doubtless your miserly old soul will be reveling in glee, and your conscience—Heavens! has such a being a conscience? Had you decently bided your time you would have been paid next week. I got the bill only a few days since, and took steps at once to pay you in full—for I did not think the medical fraternity boasted such liberality.

"Faugh! you are hardly worth wasting a stamp upon! I once felt a show of gratitude towards you, but that is gone. No such kindly feelings can exist in the overwhelming torrent of your contemptible and insulting folly. You are wanting the essence and characteristics of a gentleman, and I, too, have been compelled to step down to your level, in order to write my opinion of you. But it is for mother's sake, and I assure you, if she have suffered, I will take it out of your miserly old bones, galvanized though they are with the metallic armor of Shylock, gold and the devil. It is a pity you were not on the Mount with Satan instead of Him whom you *pretend* to imitate. Satan would not have had to wait for *your* suppliant adoration. You are a scoundrel at heart. You have insulted my mother, my wife, and myself; and I hope the recollection of it may bring the blush of shame to your weazened, but brazen, old cheeks, till you go to your grave, and repent."

A GOOD MOVE.—A number of gentlemen in Glasgow have banded themselves together for the purpose of defacing the announcements of quack doctors, which are frequently exhibited in large numbers on the walls and hoardings of the city and suburbs. They have employed a man to go round and cover over all such bills with "lamp-black;" and it is said that in doing so he will have the protection of the police. The practice initiated in Glasgow may well be copied in all our large towns.—*The Lancet*, July 10, 1875.

NOTES AND QUERIES.

TANEYTOWN, Md., August 18, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The name signed to the report of "A Case of Poisoning by Strychnia" in your issue of the 14th is Birnie, not Bivine.

Very respectfully yours, etc.,

C. BIRNIE.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM AUGUST 17, 1875, TO AUGUST 23, 1875, INCLUSIVE.

COOPER, GEO. E., SURGEON.—Leave of absence extended fifteen days. S. O. 166, A. G. O., August 18, 1875.

STERNBERG, G. M., ASSISTANT-SURGEON.—Granted leave of absence for one month, on surgeon's certificate of disability. S. O. 151, Department of the Gulf, August 14, 1875.

WILLIAMS, J. W., ASSISTANT-SURGEON.—Granted leave of absence for one month, with permission to apply for an extension of two months. S. O. 159, Department of Dakota, August 17, 1875.

"AUGUST 14, 1875.

SATURDAY, SEPTEMBER 4, 1875.

ORIGINAL COMMUNICATIONS.

THE USE OF REVULSIVES IN DISEASES OF THE NERVOUS SYSTEM.

BY ALLAN McLANE HAMILTON, M.D.,

Lecturer upon Nervous Diseases at Long Island College Hospital; Member of the American Neurological Association, etc.

DR. WEIR MITCHELL, in his very interesting clinical lecture* upon the Value of Rest in Affections of the Nervous System, says, "To be small one moment and large the next is a condition of health for the vessels." We recognize in most of the different neuroses of circulation a departure from this rule, and the treatment of these I especially propose to discuss. In congestion of nerve-matter, the vessels are deprived of their normal property, losing contractility undoubtedly through a paralysis of their vaso-motor fibres, which allow the inhibitory fibres to influence dilatation. The wise provision of nature, perivascular spaces in the brain-substance, first demonstrated by Robin and His, to some degree prevents sudden changes of diameter and consequent pressure of brain-matter; so where there is constant alteration of calibre attendant upon congestive diseases, the absorption and reformation of perivascular fluid must be seriously interfered with and the functional activity of the brain impaired. In the various diseases of the brain and cord dependent upon increase or diminution of blood-supply, the meninges of these organs must be affected to produce changes in the circulatory vessels of the nerve-substance itself. We may accomplish this best by revulsive applications to the back, so that there may be decided impression made upon the sympathetic ganglia and sudden shock to the vessels of the meninges, or by irritation of peripheral ends of spinal nerves, and inhibitory action as a consequence.

Brown-Séquard† recently stated that he had observed, after application of the actual cautery to the skin over the cervical sympathetic ganglion, a marked effect upon the iris, through stimulation of the ciliary filaments. We may, therefore, take for granted that vaso-motor filaments of other parts are influenced as well. The repeated transmission of reflex impression or sensation of a healthy character should be followed by a beneficial change in the nerve-substance. We observe in peripheral neuralgia that if irritation be made between the point of morbid sensation and the nerve-centre, the disease will be cured through a change in the character of the abnormal sensation sent from the periphery.

We are enabled to put this principle in play when pain results from disordered central action, such, for instance, as spinal irritation dependent upon anæmia. The revulsive action of certain agents will change the character of the trouble by first transmitting a reflex impression, or, second, altering the

circulation‡, through changes in the contractility of the arterioles.

Brown-Séquard† has shown the striking results following the use of revulsives in diseases dependent upon loss of trophic function, more particularly the wonderful reparative process that follows the alternate application of heat and cold to bed-sores. This condition is eminently a neurosis, and the results of this form of treatment must clearly justify the conclusion.

For the production of the revulsive effect, we must bear in mind the important fact that application of the agent must be sudden and superficial. By observing these conditions we produce what is necessarily a shock.

Two forms of application which I consider of great value are, first, the actual cautery; second, the alternation of heat and cold. The use of the first in my hands during the past year has convinced me that for certain neuralgias no better remedy exists. Not only has it broken up attacks, but it has also most certainly brought about central changes resulting in healthy action of those parts.

Dr. William H. Thompson§ prefers the glass rod heated instead of the white-hot iron; and for convenience, perhaps, it is the better of the two. As far back as 1823 it was employed by Van der Kolk in epilepsy, with decided success; but he used it to produce a lasting ulcer, and not as an agent for obtaining a sudden and superficial irritation: nevertheless, he reports several cases, six in all, that were greatly relieved, and one cured entirely.

Delpech recommended the actual cautery for neuralgia, but kept up a running sore.

The late Dr. Anstie|| seems to have been the first person who used the cautery-iron with a proper idea of its effects; and he abandoned the theory that it acted only as a counter-irritant. Anstie's opinion of its action, which is undoubtedly the correct one, is based upon the fact that the impression interrupts the conductivity of the nerve which is between the point of disease and the centre. Consequently, what I have said before about its being applied (not at the seat of pain, but between its focus and the nerve-centre) is the rational method.

I have often watched the truth of this in cases of facial neuralgia dependent upon carious teeth, sometimes by destroying the character of the morbid irritation, and supplanting it by the actual cautery impression; we may then have a new sensation transmitted to the sensory centre which is beneficial. In those cases of neuralgia where there are hyperæsthetic points, the actual cautery holds out a very good chance of relief. In epilepsy, when an *aura* precedes the attack, the burning of a part of the skin between the point from which it starts and the nerve-centre will abort subsequent seizures.

Much depends upon the temperature of the iron. It is absolutely necessary that it should be brought to a white heat. A red-hot iron will produce deep

* Rest in Nervous Diseases, Am. Clin. Lectures, p. 86.

‡ Central Nervous System, p. 261.

§ On the Treatment of Sciatica, Am. Clin. Lec., p. 110.

|| Neuralgia, etc., p. 286.

action, and will destroy tissue by subsequent ulceration; the same results will follow the *slow passage* of the iron over the surface. The cautery-iron should invariably be white-hot: it should be drawn rapidly over the skin, and the result will be almost painless. The surface will be slightly discolored, and that is all, as the action is confined to the cuticle, which shrivels up and falls off in a few days. There has been a tendency of late to use the cautery-iron in convulsive affections, and it has been my privilege to see several patients who have gone through this ordeal without any benefit whatever, and have had their troubles aggravated by the nervous apprehension and dread associated with the white iron. As I have said before, the neuralgias are the neuroses that call for its use. I may relate the following case, which will illustrate the efficiency of superficial cauterization for sciatica:

Mr. F., twelve years ago, when a clerk, was obliged to sleep in the damp bedroom of a warehouse near the river. He then contracted a "cold" with attendant "rheumatism," and a condition was left which was unmistakably sciatica.

He consulted several medical men, among them one in this city, who suggested a blister. This acted beneficially, and the disease disappeared almost entirely. With every change of the weather, however, he had some reminders of the malady, and finally, in the spring of 1874, he was prostrated, and took to his bed. When I examined him I found marked atrophy of the affected leg, some anæsthesia, and marked contraction. Galvanism, deep hypodermic injections, and various counter-irritants, combined with constitutional treatment, had failed to do him good or abate the symptoms. I then directed his attending physician to use the cautery-iron. In three weeks he was up, and is now free from pain. The applications were made as soon as the previous burns were healed. Not only here does it act as a revulsive, but it unmistakably removes exudations that may press upon the nerve-sheath.

I have spoken of the uses of heat and cold for the relief of certain neuroses associated with trophic and circulatory defects. It remains for me to prove the efficacy of this treatment by the relation of experience; but first I wish to refer to the results of experiments by Chapman and others. We may tabulate them as follows:

COLD TO SPINE.

<i>Physiological Action.</i>	<i>Therapeutical Indication.</i>
Muscular tension is lowered.	Overcoming the convulsive contraction due to acute or chronic central neurosis.
Sensibility is lowered.	Relief of neuralgias.
Peripheral circulation increased.	Morbid conditions of sensibility associated with hemiplegia relieved.

HEAT TO SPINE.

<i>Physiological Action.</i>	<i>Therapeutical Indication.</i>
Increased activity and function of sympathetic ganglia and contraction of vessels.	Subsidence of inflammatory condition of nervous centres.

A consideration of the effects of both of these agents enables us to see that an alternate application of either would produce a sudden and beneficial change of tone, thus illustrating the words of Dr. Mitchell before quoted.

Every neurologist is overrun by a class of patients that constitute a certain *opprobrium medicorum*. These are patients with dysæsthesiæ, spinal irritation, and a few other maladies, confined chiefly to women, and dependent upon uterine diseases. After the employment of many remedies, and after finding hopeless results, constituted either by relapses or temporary improvement, the case is discharged. In these cases I found the alternate use of heat and cold to be followed by the most desirable effects, particularly in spinal irritation. Of twenty-six cases of this kind I have cured fifteen, and have greatly improved all the others. I had used phosphorus and electricity with indifferent success, but the alternate application of heat and cold to the spine produced a decided impression. I at first directed the patients to employ ice-bags, and hot flat-irons covered by flannel, but subsequently made use of the instrument I will presently describe. In hysterical affections this mode of treatment was of great use, particularly those forms characterized by lividity of the surface and unconsciousness, with rigidity. The surface became warmer and the circulation much more equable after ten or fifteen minutes' use of the revulsor. I wish to give examples of this form of treatment.

Case I.—Patient married eight years; no children; complains of headache of anæmic variety, somnolency, inattention, loss of memory, and mental incapacity; very pale and thin, pain in back. A previous physician found uterine trouble, which was removed. Pyrophosphate of iron, strychnia, and hot and cold applications; benefit in two weeks, and cure in three months.

Case II.—Patient at present under treatment. After an acute attack of sickness (probably typhoid fever), convalescence began; some pain in the back, and tenderness on pressure; feebleness and indisposition to take exercise, tight constriction of waist, headache; somnolency continued through the forenoon; very difficult to arouse. The husband of this patient is obliged to throw cold water in her face before she will awake. Great inability to fix attention upon anything. It was impossible for her to read. Dr. Loring examined her eyes, and found paleness of optic disks. Under a systematic use of the revulsor during the first three months, these symptoms have one by one disappeared, till but few are left. Three weeks after treatment, she could read, and the headache had gone. Sleep is much better, as it does not extend over a natural period. She was in a very curious condition at night. Between the hours of eight and eleven she seemed to be very wide-awake and vivacious, but during the early part of the day she was stupid and heavy.

Other cases I might present, and would prove that the action of heat and cold begins at once, and that early recovery is to be expected. For the application of these agents I have devised the instrument figured in the cut. It consists of two chambers

of brass three inches in diameter by one and a half inches deep. These have screw-plugs inserted so that they may be removed and the chambers filled, one with cold water and salt, the other with hot water. These chambers are fixed on a rod, and separated by an insulating or non-conducting substance. The rod terminates in a handle. The flat surface covered by thin flannel is placed against the bare back, on either side of the spinous processes of the vertebræ, and the instrument is passed up and down quite rapidly. As the heated surface moves instantaneously to where the cold one was an instant before, the effect is quite marked.

Dry heat and dry cold are much better as therapeutical agents than moist heat or moist cold. The effect is energetic; the skin is influenced more quickly, as there is no fluid between to act as a non-conductor. Dr. William H. Thompson, of New York, to whom I have shown this instrument, has expressed his ideas very strongly upon this point.

A consideration of the action of other revulsive agents would take many pages. I must say a word, however, of the virtues of the localized ether-spray to the spine. I can conceive of no better treatment for chorea and other convulsive disorders. I have witnessed its effects even in convulsive disease of adults. Shaking palsy, and the tremor of alcohol and sclerosis, may be moderated. It is safe to say that fifteen or twenty applications of the spray in most cases of chorea will effect a cure. I have tested it alone and with other remedies, and in several cases it cured the disease without adjuvant treatment.

In paralytic conditions, local application of the revulsor to the muscles themselves seemed to increase the circulation in the tissues much more vigorously and successfully than did the faradic current. Dr. G. M. Beard, of New York, a year or so ago exhibited at one of the meetings of the Academy of Medicine an apparatus for applying hot air to a paralyzed limb in hemiplegia. It consists of an earthen pipe (Dr. B. demonstrated his remarks by a common earthen drain-pipe) heated to a moderate degree: this was placed about the paralyzed member. His results were good. Heat and cold I am convinced are valuable remedies that have not been thoroughly made use of.

MEMBRANOUS CROUP: TWO REMARKABLE CASES,

SHOWING THE EFFICIENCY OF MEDICINAL AGENTS BOTH IN THE CURE AND ARREST OF THE MALADY.

BY J. J. MAGUIGAN, M.D.

THE subject of the first case is a male child, two and a half years of age, whom I saw at 8 P.M., twenty-four hours after the onset of the disease.

He presented that assemblage of phenomena so characteristic of laryngeal obstruction,—namely, contraction of the lower part of the chest, with sinking in of the soft parts above the clavicles and the sternum in the act of inspiration, which was slow, laborious, and stridulous; the voice was husky; the facial expression wild, anxious, and appealing; pulse 130, and fever pretty high. There were no exudation-patches on the fauces. Spasm was a prominent and aggravating factor in the dyspnœa.

Coxe's hive syrup having been administered without effect, I ordered a heaping teaspoonful of alum, dissolved in sweetened water, which provoked emesis. This eased up his symptoms to a degree by subduing the spasmodic element against which it was directed.

At 10.30 P.M., two hours later, I returned, and found that he had steadily grown worse, there being now an exaggeration of all the portentous phenomena aforementioned, and higher fever. I again administered an emetic of alum, and then ordered nauseating doses of ipecac, $\mathfrak{z}\text{i}$, to be repeated every hour, with large mush-poultices to the neck, and further directed that about two o'clock another emetic should be given.

About five o'clock of the morning I was again summoned to the child. He had now reached the very climax of his suffering, and was in the jaws of death. He lay on his side, with his head violently retracted, stretching the trachea to its utmost limits in a superhuman effort to carry on respiration. I heard for the first time a soft, shifting rhonchus in the larynx.

I cleared the fauces of a quantity of mucus and blood by provoking reflex action in the part with the handle of a spoon, and then gave an emetic of thirty grains of the sulphate of zinc. The vomit contained mucus and blood, broken bits and flakes of white membrane, and one large fragment an inch in length and several lines in breadth.

Considerable relief, of course, followed the expulsion of these matters, but the relief was relative, not absolute; the symptoms were still alarming, and it was manifest that the great bulk of the membrane, nearly all, in fact, remained firmly adherent in the throat, though a feeble flapping sound—the *tremblement* of the French—could be heard in the larynx on inspiration.

With a view to the speedy softening and detachment of the membrane, I placed under the nostrils of the child a cup of slaking lime, a practice strongly recommended in the text-books and in the didactic lectures of the course. The experiment, in my hands, was unsuccessful and unfortunate. In the first trial the fumes arising from the lime nearly suffocated the child: he tossed his head wildly about in search of a breath of pure air. In the second trial, and even in the third, the dyspnœa was equally aggravated.

I then directed the atmosphere of the room to be charged with vapor-steam generated from a caldron of boiling water placed over the fire. The apartment was a contracted one, 10 by 14, and was constantly occupied by at least three or four of the

sympathizing friends of the family. In an hour afterwards, on my return, I found the air saturated with moisture, but the child was worse, his face flushed, wild, and excited, and the dyspnoea frightful. I instinctively opened the doors and windows, letting the fresh air in or the bad air out, to the manifest relief not only of the child, but also of the other panting inmates of the apartment.

These methods proving unavailing or inapplicable, I next tried a *hand-ball atomizer*, the kind used for perfuming handkerchiefs, and, filling it with lime-water, I played a beautiful spray into the fauces and larynx for at least five minutes. For the first time my efforts seemed to have met with a favorable response. In an easy manner this instrument accomplished the conjoint objects sought to be attained by the other two methods,—viz., the application to the larynx of moisture and a substance capable of acting chemically upon the membrane and dissolving it. The lime-water, which was the official solution, was used cold. The spray was employed half-hourly for the next twelve hours, and then hourly until convalescence was declared. The relief which it afforded, as indicated by the diminished dyspnoea, was always prompt and decided, particularly after the first few applications, when the membrane began to evince signs of rapid disintegration. The cough became less sonorous and more moist, and the expectoration free, the hawked-up matter being swallowed almost invariably. On the morning of the fifth day the larynx was entirely free. Respiration was entirely unimpeded, yet rough and croupal; the voice also remained husky, and a constant, short, laryngeal cough tortured him for the next twenty-four hours, for the relief of which a mixture of hydrate of chloral, tinct. opii, and ipecac was given. A simple catarrhal cough remained for two weeks or more.

So much with regard to the membrane, the expulsion of which may be considered the *sine qua non* to recovery; but scarcely less inimical to the life of the patient in this case was the superadded spasm. This element, though it played a subordinate rôle, would have determined the death of the patient but for the energetic manner in which its influence was combated by emetics and nauseants. By it all the frightful paroxysms of dyspnoea were superinduced. The most violent of these paroxysms, as well as a general exacerbation of the disease, invariably occurred at night on the second, third, fourth, and even the fifth night, the attack setting in at nightfall and subsiding at dawn of day. This nocturnal exacerbation and the prominence of the spasmodic element are two phenomena in the clinical history of this affection which have been fully portrayed by Jenner in his recent clinical lecture on true croup (*Medical News* for April, taken from the *Lancet* of January 16).

Throughout the treatment the child's vital powers were sustained by administering its aliment to it during the intervals of comparative quietude.

The subject of the second case was a baby eight months old, to whose condition my attention was called on the third day of my attendance on the first case by hearing from it a faint croupal cough.

An examination revealed considerable redness of the fauces, with patches of exudation on the tonsils and posterior wall of the pharynx. This, it will be observed, was an anatomical departure from the other in the incidence of the attack.

The teachings of Trousseau have always had for me a peculiar charm. I took up a stick whose end was wrapped with a bit of cotton, and, charging it heavily with powdered alum, I swept the fauces. In two hours after I threw into the pharynx with the atomizer a spray of a ten-grain solution of sulphate of copper. The baby shortly after vomited. The appearance before noticed vanished within twelve hours, excepting a slight erythema of the mucous membrane. A croupal cough with huskiness of the voice remained for three or four days.

Now let us return for a moment to the treatment, and see whether, in the rapid exfoliation of the membrane observed in the first case, the lime-water was not the principal agent. In a disease which presents such a frightful mortality of nineteen deaths out of every twenty-two cases (Dr. Ware's statistics, given by Flint), it would be absurd to ascribe the whole result to an inherent tendency. But it may be said that nature took the initiative, and already began the work of resolution. In this, however, she did no more than she always does, *i.e.*, commence an operation which she is unable to complete; in the vast majority of cases death does not occur until as late as the fifth or sixth day, when the process of resolution has advanced as far, at least, as was observed in this case. I do not question the influence of the pathological turn-point on the success of the treatment in so far as it had weakened the vitality of the membrane and opened it up to the solvent action of the lime-water.

Lime-water is an active chemical solvent of pseudo-membrane. "We have frequently found," say Meigs and Pepper in their magnificent treatise on Diseases of Children, "when fragments of firm white exudation have been placed in lime-water at a temperature even lower than that of the buccal cavity, that the exterior began in a very short time (half an hour) to undergo disintegration, and that the whole fragment was reduced in a few hours to a granular putrilage." Oertel, describing the same process upon the toughest and most solid membranes he could find, says, "After the lapse of not more than fifteen or twenty minutes, particles of greater or less size gradually separated from the membranes, and after from thirty to forty-five minutes they are completely broken down, and, with a slight agitation of the test-tube, dissolved into a turbid, flocculent fluid" (Vol. I. *Cyclopædia of the Practice of Medicine*, edited by Ziemssen).

Respecting the second case, the influence of treatment was no less striking and palpable, assuming, as we are obliged to do, that the case would have developed into croup, or an extension of the exudation into the larynx.

I append to this report the history of the following case, which just at this moment has passed out of my hands, as an admirable commentary upon some of the views therein expressed, and the value of the lime-water treatment. The subject was a

little girl, A. C., two years and a half old. When I saw her, there were patches of exudation over the tonsils and pharynx, and she had those objective symptoms of laryngeal obstruction described in the first case, but less severe.

I instituted the same line of treatment given in the first case, but, owing to the obstinacy and perversity of the child, and the want of control over her by her parents, the spray could not be employed. The treatment in every other respect was precisely identical with that given in the first case, viz., emetics and nauseants. *Resolution had feebly commenced on the third day.* The child died at 11½ P.M. of the fifth day.

1241 NORTH SEVENTEENTH STREET, May 14, 1875.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. D. HAYES AGNEW, M.D.

Reported by WM. M. MASTIN, M.D., Resident Surgeon.

ANEURISM OF THE EXTERNAL ILIAC ARTERY—COMPRESSION—CURE.

THE subject of these notes is an active, robust laboring-man, about 48 years of age, and of intemperate habits. He states that he was born in Ireland, of healthy parents, and came to this country some fifteen years ago. His own health has always been perfect, allowing him to follow constantly his occupation—that of a ditch-digger—up to the time of his present disease.

About nine months since, while making a short journey on foot, he tripped and fell, sustaining a slight sprain of the right ankle-joint. This was soon followed by swelling and pain, extending up the inner side of the thigh to the pelvis, with a perceptible limp in his gait. However, with the exception of these erratic pains, which have continued ever since, there was no evidence of any other injury until four months later, when he noticed a pulsation in the right groin, and, on closer inspection, discovered a small tumor about the size of a chestnut.

His medical adviser, whom he at this time consulted, directed perfect rest, with elevation of the limb; but, notwithstanding the strict observance of these measures, the pulsation grew more forcible, and the tumor gradually increased in size until it has attained its present dimensions. With this history he was received into the surgical wards of the University Hospital, May 14, 1875.

At the time of his admission, inspection reveals a distinct but rather diffused swelling of the right groin, with a slight sulcus or groove obliquely crossing it a little below its middle, corresponding to Poupart's ligament; the tumor has an expanding or heaving movement. What appears to be a diffused swelling is found by palpation to be a circumscribed tumor, elastic and compressible, with tolerably thick walls, and having a pulsation synchronous with the action of the heart. This tumor is about four and a half inches in length. Taking Poupart's ligament as a line, it extends from a point two and a half inches above the middle of that ligament to two inches below it. Laterally, the diameter is almost the same: the tumor reaching from half an inch to the inner side of the anterior superior spinous process of the ilium to very near the mesial line.

On placing the ear over the tumor, the characteristic bellows-sound or aneurismal bruit is plainly heard.

This murmur extends for a short distance into the sound portion of the femoral artery.

Cutting off the supply of blood to the part by compressing the abdominal aorta, or thrusting the primitive iliac back against the brim of the pelvis, stops the pulsation, making the tumor subside in a measure and grow sensibly smaller. No disease of the heart or large arteries can be detected by careful auscultation; but, on examining the pulse on the two sides, the right radial artery is found to be extensively atheromatous, feeling like a stony mass beneath the finger.

Remembering the man's occupation, and the habit these men have of using the long-handled spade for their work and making the upper part of the thigh act as a fulcrum upon which the handle of the spade rests in throwing up the earth, I find the tumor occupies about this position, and, perhaps, may have been caused by this pressure and strain on the already diseased artery.

In view of this diseased condition of the man's arterial system, compression of the artery was decided upon as giving the best chance of cure. Accordingly, as a preparation for this procedure, he was placed on light diet, and the leg elevated on an inclined plane, with directions to have the bowels thoroughly emptied.

May 17.—At 7.05 P.M., pressure was begun by an abdominal tourniquet, the pad of which compressed the common iliac. The man stood the pressure until 10.45 P.M., when the pain was so great as to necessitate the administration of ether. Under the influence of this anæsthetic, compression was continued one hour and fifteen minutes longer, when the tourniquet was removed. After the removal of the tourniquet the pulsation was found to be somewhat lessened, and the walls of the tumor thickened, firmer, and less elastic. Patient complained of tension and stiffness in the groin. Elevated the leg, and quiet enjoined.

May 20.—Pulsation and general condition of tumor remained unchanged.

May 22.—Compression again commenced. 2.45 P.M., artery completely occluded. Pain required the early administration of ether. 6.45 P.M., pressure let up for a moment, and pulsation found to be much lessened. Temperature of leg tolerably good, but enveloped it in cotton batting. 2.45 A.M., tourniquet removed entirely. Pulsation still more diminished. Tumor continued to grow hard and more resisting. Temperature of leg remained good. Patient eleven hours and forty-five minutes under influence of ether.

May 26.—Consistence and impulse of tumor remained unchanged, but tumor seemed to be growing larger, as it had encroached on median line. The iliac was more involved.

May 29.—Put patient under ether and compressed abdominal aorta, cutting off blood from both extremities for one hour and ten minutes. After the hour the tumor seemed almost solid and impulse scarcely discernible.

May 30.—Compressed abdominal aorta for a short time, at the expiration of which, impulse in tumor had entirely ceased, and tumor perfectly solid and firm. No pulsation in femoral. Temperature of limb excellent. Continued with warmth to and elevation of the limb.

June 2.—Tumor remained a hard, solid body. Pulsation returned in popliteal artery. Patient in an excellent condition.

June 6.—Patient discharged cured.

A PROPHYLACTIC FOR SORE NIPPLES (*The Medical Record*, August 21, 1875).—Dr. Julius Fehr recommends the local use of tannate of lead and glycerin, two or three times daily for about one month before parturition, as a reliable preventive of sore nipples.

TRANSLATIONS.

PENETRATING WOUND OF THE CHEST—RECOVERY (*Le Mouvement Médical*, August 7, 1875).—M. Hervieux reports the case of a young man who, with the intention of committing suicide, stabbed himself with a knife in the fourth intercostal space immediately above the upper edge of the fifth rib, one and a half centimetres below the left nipple and eight centimetres from the left border of the sternum. The blade penetrated the thoracic cavity to the depth of nine centimetres. When first seen, he was covered with blood, the clots, which were then hastily removed, weighing between two and three pounds. The wound was quickly cleaned, three pins were passed from one side to the other, and it was then accurately brought together by a twisted suture, thus arresting all external hemorrhage. In a few moments, however, a thrombus the size of a hen's egg formed at the external angle of the wound, and outside of this and below it there was developed an elastic and tympanic tumor, which was about as large as two fists, and was due to subcutaneous emphysema. These, however, remained stationary. The pulse was then only eighty-four a minute, but was soft, feeble, compressible, intermittent, and irregular. Respiration was high and frequent, and each inspiration was accompanied by a sharp pain at the bottom of the wound. His face was pale, almost exsanguine. He had neither cough nor bloody expectoration. Cold compresses were applied over the wound, followed later in the night by poultices of flaxseed meal. The following day the emphysema had disappeared; the thrombus still persisted; there were fever and dyspnoea. On auscultation nothing abnormal was found on the affected side. On the fourth day the pins were withdrawn, and the wound was found to have united by first intention. His convalescence was uninterrupted, and in three weeks he was entirely well. M. Hervieux concludes that the heart had just escaped being wounded, but that the knife must undoubtedly have reached the lung, although the thickness of the left side of the heart separating the lung from the anterior wall of the chest probably caused the wound to be of but slight depth. He admits the absence of a certain number of positive signs which we are accustomed to associate with a pulmonary wound, but refers to several cases in which the diagnosis was beyond question, and in which, as in this one, there was neither cough, bloody expectoration, pneumonia, nor pneumothorax, and recovery was equally speedy and uninterrupted. J. W. W.

URÆMIA IN CANCER OF THE UTERUS (*Le Progrès Médical*, July 24, 1875).—M. Raymond reports the case of a woman, æt. 50 years, who died of cancer of the uterus. During the last four days of her life she urinated with difficulty, and had a profuse diarrhoea; coma had preceded death for forty-eight hours. At the autopsy the right ureter was found to be compressed by the uterine cancer. The kidney of the same side was much atrophied in its substance proper, but its pelvis was considerably enlarged. The two ureters were large, and contained a clear citron-yellow watery fluid, which on analysis was found to be composed of water .977, urea 3.85, albumen 7.60, alkaline chlorides 6.10, phosphates, sulphates, etc., 5.45. The experiments of Hermann demonstrate that the proportion of urea in the urine diminishes relatively to the volume of the latter when pressure is made on the ureters, and when this pressure is equal to that of sixty millimetres of mercury the urea disappears altogether. It is easily understood, then, why women suffering from cancer of the uterus still pass a normal quantity of urine, which, however, is only water, when there is incomplete compression of the ure-

ters, and why also they die of uræmia. These facts have been verified in several cases at the Salpêtrière.

J. W. W.

SALIVARY CALCULUS THE CAUSE OF AN INFLAMMATION OF THE VELUM PALATI AND THE BASE OF THE TONGUE (*Le Progrès Médical*, July 10, 1875).—M. Gouguenheim reports the case of a man æt. 35, subject to winter cough, but presenting neither the rational nor the physical signs of tuberculosis. He complained of a pain in the throat, at first slight, but becoming more and more intense. There was a slight redness of the soft palate and its arches, but no change in consistence could be recognized by the touch. The pain became more severe whenever, during the examination, the base of the tongue was depressed. He was tormented by incessant movements of deglutition, and complained of a continual spasmodic sensation in the throat. At the end of four days the pains, which were growing intolerable, suddenly ceased, after the evacuation of an elongated cylindrical concretion, a little more than a centimetre in length. It was of a dirty-yellow color, and was formed of a number of layers of organic and inorganic matter disposed in a concentric manner. It was found on examination to be a salivary calculus, and had probably been lodged above the aryteno-epiglottidean folds or behind the greater cornu of the hyoid bone. J. W. W.

HEPATITIS (*Le Progrès Médical*, July 24, 1875).—M. Cornil has had the opportunity of studying the livers of patients who had died from a parenchymatous hepatitis occurring in the course of such diseases as leucocythæmia, typhoid fever, smallpox, etc. He has found in these cases a lesion analogous to that which he had already pointed out in certain cases of cirrhosis. The smaller intralobular biliary canaliculi were filled with epithelial cells, placed end to end, and which finally obliterated them. As these alterations are especially marked in the smallest peripheral canals, it is evident that the bile produced in the central canals cannot escape if the lesion is much advanced. The mode of production of the jaundice is thus explained: it is due to the disease of these canaliculi, and not to obliteration of the large biliary ducts, as generally believed. J. W. W.

CYSTIC ENLARGEMENT OF THE APPENDIX VERMICIFORMIS (Dr. Wenzel Gruber: *Virchow's Archiv*, lxi.).—In a series of cases of cystic enlargement of the processus vermicularis, the following, which was found in the body of a man who died of tuberculous disease of the lungs and intestines, is deemed worthy of notice.

The process at its lower portion was distended into a round sac with thick walls, while its upper portion had been transformed into a thick pedicle, through which there was a canal of small calibre. At its attachment to the cæcum it had been converted into a short tube of large size but with thin walls, and which represented the neck of the tumor, being connected below with the sac and above with the cæcum and the canal in the pedicle. The sac contained a quantity of stringy compact mucus, which tightly distended it.

The larger part of the ring-shaped opening of the sac was joined to the omentum majus by adhesions, but there were no connections between the tumor and the peritoneum lining the upper part of the iliac fossa. The orifice between the gut and the appendix must have been of small size before any pathological changes took place, but had perhaps been rendered much smaller by the chronic inflammatory processes accompanying the tuberculous ulceration which had been taking place.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 4, 1875.

EDITORIAL.

A NEW HAPPY FAMILY.

THE establishment of a homœopathic hospital in New York has given a good-natured contemporary the opportunity of congratulating thereupon the followers of Hahnemann, the practitioners of opposing schools of medicine, and the public at large, and, like Mark Tapley, of "coming out strong" under rather unfavorable circumstances. It bases its cheerfulness in the matter upon the doctrine of the survival of the fittest, holding that if homœopathy is what we believe it to be, it will certainly be annihilated in the professional struggle for existence, and all the sooner for being brought into greater prominence and more active competition. We heartily coincide with these views, which are doubtless correct; but when it also looks forward hopefully to the appointment in connection with the same institution of a sort of supervisory or consulting board, to be composed of regular practitioners, who are to make the diagnoses, and, when the issue happens to be a disastrous one, are to verify them by "autopsical examination," we cannot share its sanguine anticipations. The adoption of the proposed plan would leave our homœopathic brethren sandwiched, as it were, between two layers of what they would term "allopathy," with merely the privilege of administering their attenuations and observing their effects or the absence of them; while, on the other hand, the consultant or diagnostician would frequently have to stand aloof and witness what would be, according to his views, the

needless sacrifice of human life, with the unpleasant feeling of being morally, if not legally, *particeps criminis*. We can imagine one of our venerable professors, a believer in counter-irritation, revulsion, and venesection, having, for example, made a diagnosis of congestive hyperæmia of the brain, threatening apoplexy, in a plethoric subject, modestly retiring into the background while his infinitesimal brother steps forward, consults his list of symptoms, and administers the hundred-thousandth dilution or trituration of what he conceives to be the appropriate remedy, after which, according to the "contemplated" programme, the patient would probably pass again into the hands of the "old school."

It seems somewhat unjust to exclude the other medical sects from the benefits of this new co-operative association, and we would suggest resigning the "autopsical" department to the Thomsonians, allowing the eclectics to sign the death-certificates, and requesting the "medical electricians," "cancer-doctors," and "herbalists" to attend the funerals in a body. The female doctors would have to be assigned to some department of importance and responsibility, or the managers would be overwhelmed with petitions and memorials. The "practical physicians," the "healing mediums," the "seventh sons of seventh sons," the "pow-wows," *et id genus omne*, whose services could probably be secured, and with equal propriety and judgment, would still remain to be provided for. Then would come to pass the saying which is written, "The wolf also shall dwell with the lamb, and the leopard shall lie down with the kid; and the calf and the young lion and the fatling together."

It must be understood, however, that the first-mentioned scheme of a board to make diagnoses and autopsies is not merely visionary or hypothetical, for we are told that "a plan having such an end in view is already under contemplation by the Commissioners of Charities and Correction," who, we believe, will be the managers of the new hospital.

We fear the commissioners will have to "contemplate" for an indefinite period before they find, even among the homœopaths, the necessary ignorance and imbecility upon which to base such an arrangement, and we feel sure they would encounter a still greater difficulty in persuading reputable physicians or surgeons to serve upon the diagnostic and "autopsical" board.

Seriously, although we do not view the acquisition of this new institution by the homœopaths as of any importance to the medical or scientific world, and believe it to be predestined to the obscure fate

of its predecessors in other cities, yet there is one aspect in which the matter assumes a gloomy significance. When we remember the intellectual status of the men to whose care, under its auspices, human lives will be confided, and when we recall the list recently published in one of our daily papers, of cases neglected and maltreated at a similar institution in this city, we cannot but feel that the experiment is almost too costly.

We can see no more reason why a homœopathic practitioner should be allowed the opportunity of demonstrating his lack of common sense at the cost of suffering humanity than why any of those more generally recognized as quacks should be allowed the same privilege; and our contemporary's suggestion that we should "combat error on the common ground of reason and the broad platform of enlightened liberality" applies with equal force to all who practise by an exclusive dogma.

LEADING ARTICLES.

THE INFLUENCE OF THE LOWER ORGANISMS IN THE PRODUCTION OF INFECTIOUS AND CONTAGIOUS DISEASES.

II.

HAVING in the earlier portion of this article given some account of bacteria in general, it now remains to follow up, so far as possible, the progress of investigation as regards the influence of these organisms on disease, and to examine the present state of our knowledge concerning this influence.

In doing this we shall take up in the first place the subjects of pyæmia and septicæmia, since it was in regard to the occurrence of the lower organisms in these conditions that the earlier investigations of their action were made.

The frequency and gravity of septic complications of wounds have made their etiology, pathology, and treatment one of the most important and interesting of all surgical problems, and the scanty success which has thus far attended all prophylactic and remedial measures shows that the problem in part, at least, is still unsolved.

The intimate connection between putrefactive processes and the group of symptoms called septicæmia has been regarded as established since the celebrated experiments of Gaspard.* Their cause was at first supposed to lie in the absorption of the pus of the wound through the open mouths of the several vessels; then in poisoning of the blood by pus formed in the interior of the vessels by phlebitis. Piorry about 1835 gave a full and accurate account of those symptoms to which he afterwards gave the name septicæmia, by which they have

since been known. He ascribed the disease solely to the effects of the absorption of putrid matter through the lungs, skin, intestine, or the surface of a wound, but did not attempt to discover the source of its virulence.

Panum, in 1856, spoke of a non-volatile septic poison which is insoluble in absolute alcohol, soluble in water, and not destroyed by prolonged boiling. Robin considered the virulence due to a catalytic effect produced upon the humors and tissues of the body by contact with a substance in which putrefaction had brought about an isomeric change in the fundamental "immediate principle." He said, "Putridity is not virulence; on the contrary, when it has advanced to a certain degree it destroys virulence;" a statement now universally accepted. Bergman also took the same view, believing the toxic action of putrid substances to be due, not to inferior organisms, but to a diffusible nitrogenized toxic substance resisting alcohol, ether, and boiling heat, and formed during putrefaction.

While thus certain investigators examined the causes of pyæmia and septicæmia from this point of view, others were not wanting who continued to maintain the bacterial origin of disease, and their views were supported by very numerous and varied experiments, to some of which allusion will now be made.

Mayrhofer (1863) claimed that puerperal fever was due to low organisms, which he called vibriones. He observed that they appear in the lochia of healthy lying-in women in small quantities on the fifth day after delivery, but in those attacked by puerperal fever, immediately after delivery, and in large quantities. Injecting a putrid infusion of meat into the uterus of a rabbit soon after delivery, its death resulted from endometritis with septicæmic symptoms.

Leplat and Jallard made inoculations with putrefying animal and vegetable infusions containing vibriones without causing septicæmic results. They hence concluded that vibriones coming from putrefying animal and vegetable substances cause no accidents when injected unless accompanied by virulent agents, which latter are alone responsible for any unfortunate results that may ensue.

The experiments of Coze and Feltz (1865), they asserted, proved that the blood of animals inoculated with putrefying fluids is itself infectious, that it contains bacteria, and that the infectious ferment gains in force by its passage through the organism. They claimed also that the organisms found in the blood are the active efficient agents in the poisoning, and they agreed with Pasteur in saying that there are two phases of putrefaction, of which only the first would cause poisonous symptoms. Hence putrefaction destroys virulence.

In 1869-72, Davaine, investigating anthrax (malignant pustule), discovered bacteridia in the blood of patients. In a report upon inoculations with putrid blood, Davaine confirmed the experience of Coze and Feltz in regard to the gain of virulence by repeated transmissions, and also the destruction of the septicæmic virus by putrefaction. Davaine's experiments received much attention, and at first his conclusions were distrusted;

* Jour. de Phys., par Magendie. T. i. p. 1, 1822, and T. iv. p. 1, 1824.

but, having been substantially confirmed by other investigators, the following points were generally conceded. 1. Susceptibility to the virus varies in different animals. 2. Putrid blood loses its virulence as it gets older. 3. Septicæmia is a putrefaction taking place in the blood of an animal, and induced by bacteria and vibriones. 4. Blood putrefied within the body is much less poisonous than that of an individual whose death has been caused by or who is still suffering from septicæmia, typhoid fever, or gangrene of the lung. 5. The one-millionth part of a drop of such blood injected into the cellular tissue of a rabbit will cause the death of the animal within twenty-four hours. 6. The poisonous quality of the blood is entirely due to the presence of bacteria.

Vulpian and Onimus contended against these conclusions; and subsequent experiments, especially those made by Billroth,* which excited universal attention, have tended to diminish the importance claimed for bacteria.

Billroth's experiments, which were chiefly clinical, were most thorough and extensive. He found in two hundred autopsies, of all diseases, coccobacteria present in eighty-seven in the pericardial liquid. The longer the interval between the time of death and the examination, and the higher the temperature of the air, the more certainly were these organisms found. Although they are found in abundance during life on many of the mucous membranes, it is probable that they make their way into the tissues and circulation only through the lungs, and that they remain, especially in the blood, in the form of germs capable of development.

Experiments made by Lewis and Cunningham, Calcutta, in 1874, upon dogs, showed large quantities of bacteria after the injection, not of a putrefying organic liquid, but of ammonia, into the peritoneal cavity.

We have thus endeavored to give some idea of the progress of investigation in this direction, but, of course, have been obliged to omit even the mention of numerous highly meritorious communications or monographs. The very recent literature of the subject is voluminous. Birch-Hirschfeld,† to whom we are very considerably indebted for the facts and discussions of the present part of our article, cites no fewer than eighty-six recent contributions, most of which have been published within the last two years; and one-half of these give the results of experiments upon pyæmia and septicæmia.

And yet, what exactly do we understand by these terms? In regard to this, Birch-Hirschfeld speaks nearly as follows:

"The names septicemia and pyemia are, by many authors, used almost as if synonymous, whilst others regard these affections as perfectly distinct. When, however, the exact line of division between them has to be defined, there is very little agreement. It is

certainly true, as Virchow has demonstrated, that the morphological introduction of pus into the circulation does not result in pyemia, yet this affection is beyond doubt closely connected with suppuration. It must then be distinctly separated from the septicemia caused by putrid matter alone, and entirely unconnected with pus. Now, if it can be shown that in pyemia dependent upon suppuration the putrefaction of pus gave rise to the infection, it would certainly appear as if pyemia itself were only a species of septicemia.

"Another view, and one widely diffused, lays stress upon the occurrence of symptoms of embolic metastasis as a distinguishing point. When traumatic infection results fatally without the occurrence of metastatic emboli, the affection is termed septicemia; under the contrary circumstances, pyemia. This distinction will hardly, however, suit all cases."

We must confess that an examination of Birch-Hirschfeld's abstract of the various contributions to our knowledge of the influence of bacteria on pyæmia and septicæmia is at first not inspiring.

The forty-odd investigators reach nearly as many conclusions, and we must admit, as does Birch-Hirschfeld himself, that their position on these points is certainly very contradictory. Indeed, there are very few assertions made which, after a careful review of all the authorities, are found entirely undisputed. If, at first sight, this position of affairs seems to the seeker after truth somewhat depressing, yet we must remember that much of this work is good work and genuine. It is work of research, and not mere speculation. We hold no axiom to be more eternally true than this: that good work always pays. These facts, which now seem so scattered, so contradictory, so impossible of assimilation, will one day be found parts of a plan which, as yet, we are unable to comprehend.

The hope must indeed be regarded as illusive, that in this department the object of research is to be attained without great difficulty. The processes concerned are of such a complex nature, and our methods in many respects so inadequate, that it is hardly to be expected we shall reach at this time results which shall be entirely unquestioned.

We cannot conclude this portion of our subject better than by quoting the opinion of one of the very greatest of living pathologists, Virchow.‡

Although these remarks of Virchow particularly relate to Billroth's work already alluded to, yet they are equally applicable in many respects to the subject in general. Virchow says, "Without venturing an opinion as regards the correctness of the botanical section of this admirable work [Billroth's "*Coccobacteria Septica*"], I must confess that it agrees only in part with my own preconceived ideas upon the subject. I certainly hold as correct the idea that the ordinary putrefactive germs are sufficient to explain a greater part of the local, as well as a certain portion of the

* *Coccobacteria Septica*, etc. Berlin, 1874.

† Die neueren pathologisch-anatomischen Untersuchungen über Vorkommen und Bedeutung niederer Pilzformen (Bakterien) bei Infektionskrankheiten. Schmidt's Jahrbücher, 1875, No. 5, p. 169.

‡ Vortrag über die Fortschritte der Kriegsheilkunde, etc., besonders im Gebiete der Infektionskrankheiten. Berlin, 1874. Reprint from Allg. milit.-ärztl. Ztg., 36, 41, 1874.

general, infectious diseases. This is that province which we have always conceded, of which the highest development is septicæmia.

"The greater number of diphtheritic processes are comprised under this head, in regard to the affinity of which with putridity we have spoken long since. Their relationship is certainly closer than has been previously admitted,—indeed, closer than even Billroth is as yet inclined to admit."

Further, Virchow maintains, if pathological significance be attributed to parasitic plants, the identity of the various forms of miasma must be conceded, and it must also be admitted that this same miasma gives rise, according to the surroundings, to typhoid fever, dysentery, diphtheritis, hospital gangrene, or septicæmia. If, with Billroth, we look upon all these parasitic plants as mere vegetation-forms of coccobacteria septica, cholera may also be included here.

Only two explanations appear possible in this direction. Either the micro-organisms of all these disease-processes are identical, and it is necessary to assume poisonous substances in connection with the fungi and algæ yet distinct from these; or the micro-organisms are, *in spite of apparent similarities, different*, and form the carriers and excitors of the most serious processes in the body; they are in fact the peculiar causes of disease.

The rôle of the micro-organisms may again, under the latter view, be understood variously. Either these objects attack the living portions of the body directly, or they bring with them a poison which threatens life. This poison may either exist in the micro-organisms themselves, and they consequently be regarded as poisonous plants, or the putrefactive organisms are related to the putrid poison as the yeast-plant is to fermenting substances: they are ferments.

For the great infectious diseases, Virchow is inclined to the last-mentioned hypothesis. These distinct poisons are separable from the micro-organisms which have excited them.

It may easily be believed, therefore, that a mass of fungi (*pilzherde*) may collect at a point of inoculation or of wounding in the human body, which may secrete poison the amount of which might be sufficient to put the whole body in jeopardy, without the fungus itself being taken up by the blood.

According to Panum's researches, septicæmia cannot be referred to *mechanical* disturbance by means of micro-organisms. It does not follow upon this, however, that the excitation of putrefactive poisoning is possible without the presence of putrefactive germs. *On the contrary, the more we investigate, the more evident it appears that it is indeed the organisms themselves which cause the mischief.*

In putrefactive processes the micro-organisms may easily be identified, and their influence upon the progress of decomposition may be conveniently observed. The difficulty of understanding the pathological significance of these processes would only be insuperable *if in fact a single plant* produced the various

forms of putrefactive organisms. Here, however, practical research in regard to the physiological and pathological action of the disease-germs is decidedly in opposition to morphological research.

If these form-elements cause different effects, they themselves must be essentially different. We cannot, it is true, directly see these essential (innate) differences in such minute organisms; but we must remember that neither can we tell, from the germinative cells of the egg, numerous pathological growths, etc., what may come out of these. If it happens by inoculation that through bacteria which resemble those of the usual putrid infusions malignant pustule arises, while the bacteria of the usual putrid infusions do not cause this, then we must conclude that the bacteria of malignant pustule must be at least as different from those of infusions as hemlock from parsley.

So much for the influence of bacteria in the production of pyæmia and septicæmia. In the third and concluding portion of this article we shall examine the present state of knowledge respecting the production of other affections by the agency of the lower organisms.

CORRESPONDENCE.

NEW YORK, August 20, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DR. ERSKINE MASON, who has been especially interested in the subject of intestinal obstruction, and has performed a number of operations for its relief, recently operated in a case of carcinoma of the rectum. The fæces passed had been gradually becoming more and more attenuated, until they ceased altogether to come away, the bowel being entirely occluded. The lower portion of the cancerous mass could be felt by the finger about one and a half inches within the anus. A number of well-known surgeons were present at the operation, which was performed at Roosevelt Hospital, where Dr. Mason is one of the attending surgeons, and which was that of lumbar colotomy, for the purpose of establishing an artificial anus. The patient rallied well after it, and the procedure will, no doubt, prolong her life for some time; though the disease is steadily advancing, and has now involved the uterus to some extent.

Just at the conclusion of the operation, Prof. Alonzo Clark walked into the amphitheatre, and was politely asked by Dr. Mason if he would not like to make a digital examination of the diseased parts. The old gentleman, looking around complacently on the others present, some of whom were still lugubriously sniffing their fore-fingers, from which soap and water had been quite ineffectual in removing the disgusting odor, replied, in the driest possible manner, "No, I thank you, doctor; I am quite willing to take the word of my friends here."

The third annual report of the visiting committee for Bellevue and other public hospitals of New York to the

State Charities Aid Association, for the year ending February 1, 1875, has been published, and contains much that is interesting.

We have only time, however, to glance at a few points in the report of the committee on the Training School for Nurses at Bellevue Hospital, which is contained within the other. The school has been in operation for two years now, and seems to have more than fulfilled the expectations entertained in regard to it in the beginning. "The most conscientious and most intelligent of our nurses prove our most cheerful workers," says the report. "They fully realize that there is no such school for a wide and varied experience as just such a hospital affords. They appreciate very highly the bedside instruction kindly and constantly given by the physicians and house staff, and they know that the profession they are acquiring by persevering work in the wards will be, in their future lives, as lucrative as it is useful and womanly."

During the past year the number of wards under their charge was increased from five to nine,—now comprising three female medical, three female surgical, and three male surgical. "The fact that these four new wards," continues the report, "were urged upon our acceptance by the physicians in charge, who have watched the work of the school in the hospital from its commencement, would seem to prove their approbation of its results, and their appreciation of the difference between the services of intelligent women striving day by day to perfect themselves in a deliberately chosen profession, and the labors of the uneducated and often overworked nurses who have charge of the wards outside of the school."

The number of pupils has increased to such an extent that the house rented in Twenty-sixth Street near the hospital for the nurses' home will no longer accommodate them, and it has been found necessary to occupy a portion of the house adjoining also.

During the year one hundred and seventeen applications for admission to the school were received, either personally or through letter. "In many cases," says the committee, "the applicants fell below our standard, mentally or physically, or were prevented by domestic reasons from binding themselves to any given length of service. But generally the two years that we demand from our probationers is the stumbling-block. The thoroughness to be learned by one year's faithful work in the wards and a second year spent in training others, thus gaining the valuable experience only possible to acquire by putting knowledge to the practical test of use, counts as nothing with most American women; and it is this contentment with a superficial rather than with a thorough education that has so far proved one of our chief troubles."

Of the one hundred and seventeen applicants, twenty-nine were accepted. At the close of their month of probation, nine left,—five as entirely unfitted for the work, one as unwilling to do night duty, two for want of health, and one because she could not live apart from her family. One of the pupils who entered the

school in 1873 was dismissed, two broke their written pledges and left, and one is now superintendent of the Boston Training School.

As long as there were lying-in wards at Bellevue, the school had charge of them; but last summer, on account of the continued prevalence of puerperal fever, the obstetric service was entirely transferred to Charity Hospital.

In December, at the request of the committee, Drs. Bryan and Murray, of the house staff, held an examination of such of the women as had been in the school one year or over, and made the following report upon it: "According to request, we have examined the head nurses, asking them such questions as would give us a fair estimate of their knowledge of nursing. Supposing 100 to represent perfection, and 75 the lowest mark a nurse could have and pass, we have marked them as follows: 1, 99; 2, 98; 2, 97; 5, 95; 1, 93; 1, 90; 1, 88; 1, 85. As our marking plainly indicates, we have found them all well informed on the subject of nursing, considered theoretically; practically, we have had personal experience with all of them, and can say from actual knowledge that each one is thoroughly competent to take charge and perform all the duties of either a surgical or medical ward."

The Medical Board of Bellevue, composed of the attending physicians and surgeons, also passed a formal resolution expressing their appreciation of the improvement in the care of the sick and injured in the wards of the hospital under the "trained nurses," and their approval of the efforts of the managers of the school, in the success of which they believe that not only the hospital will be benefited, but also that facilities will be offered to the public for procuring competent private nurses. These, indeed, were the two great aims which the managers had in establishing the school: first, to make this great hospital a place where the respectable poor could be tenderly and skilfully nursed, and where even the most degraded of paupers would be sure of kindly and patient care; second, the training yearly of a band of experienced, obedient, devoted nurses for service in private cases, or among the poor.

During their second year such of the women as the superintendent can best spare from their work of training probationers are sent out to private cases, and in the year past twelve of the nurses were thus employed. In the hospital, each ward under charge of the school is worked by one head nurse, who receives sixteen dollars a month wages, and two probationers, each of whom receives ten dollars.

Since February, 1873, the school has received nearly twenty-five thousand dollars; but its annual expenses now amount to about twelve thousand dollars. During the past year the following lectures were given: "On Food for Children, and the Care of the New-Born," by Dr. Beverly Robinson; "The Eye," by Dr. R. H. Derby; "Fresh Air, Emergencies, Digestion, and Food," by Dr. Allan McL. Hamilton; "Testing Urine," by Dr. Ordronaux; "The Circulation," by Dr. Farrington; "Surgical Instruments, Preparations for Opera-

tions, Erysipelas, Gangrene, and Pyæmia," by Dr. Frank Hamilton; "Bandaging," by Dr. Brooks; "Symptoms of Disease, Puerperal Women, etc.," by Dr. Murray; and "Medicines, Inflammation, Hemorrhages, etc.," by Dr. Bryan.

At Charity Hospital a number of judicious and much-needed reforms have recently been instituted, which have been productive of great advantage to it; but a great deal still remains to be done. Thus, there are not infrequently deficiencies in bedding, clothing, medicines, instruments, appliances for nursing, and daily food, such as beef, mutton, and milk, which are attributable neither to negligence on the part of the Medical Board nor to the Warden or Chief of Staff, but to the "Medical Inspector," to whom all requisitions go, and who is vested with the privilege of cutting them down or striking them off altogether, without being required to visit the institution from which the demand comes, in order to investigate its necessities, or to state the reasons for his action either to the official making the requisition or to the Commissioners of Charities. It is claimed that a medical inspector is indispensable; but the inspector should not be an autocrat, responsible to no one, and valued solely for his skill in cutting down supplies, for his economical measures necessarily recommend themselves to his superiors, who seem to regard him as a most valuable check upon the supposed extravagance of the physicians and hospital officials.

This same false system of economy, we learn, is seen in the regulation of the water-supply. The Croton water is brought to the hospital, and the inmates are entitled by law to the use of eighty gallons a day each; but to force such an amount of water through the building would demand the use of more fuel than is authorized, and consequently there is often foul air from the closets in every ward, and the whole hospital thus tainted. Another great abuse is the necessary overcrowding of the wards at times. Thus, during last winter one ward with thirty-four beds contained forty-one patients; another, with thirty-two beds, fifty patients; and a third, with twenty-eight beds, forty-four patients.

On the 1st of August a training-school for nurses, entirely independent of that at Bellevue, though on the same general plan, was inaugurated at Charity Hospital. It is under the direction of the Commissioners of Charities and Correction, and it is the design of its originators that it shall afford a thorough course of instruction, both theoretical and practical. The age of the applicants must be between twenty and thirty-five years, and none but those of irreproachable character and sound constitution are allowed to enter. After a pupil is once admitted to the school, the attendance for the full time is compulsory, unless it should become necessary to dismiss her. The wages are to be ten dollars a month for the first year, and fifteen dollars for the second. The course of instruction is limited to two years, at the end of which time those who are found thoroughly competent will be presented with a diploma, testifying to their experience and formally qualifying them for their calling, which is to be signed by the

Medical Examining Committee and the Commissioners of Charities and Correction. During August and September lectures are to be given on "Nursing," by Dr. D. H. Kitchen; "Midwifery," by Dr. W. R. Gillette; "Physiology," by Dr. L. M. Yale; "Surgical Dressings," by Dr. J. W. Howe; "Examination of Urine," by Dr. H. G. Piffard; "Hygiene," by Dr. E. Frankel; "Care of Children," by Dr. J. H. Ripley; "Food," by Dr. Pallen; and "Poisons and Antidotes," by Dr. Drake.

In a communication on the water-supply of New York, addressed to Mayor Wickham this summer by Gen. Fitz-John Porter, Commissioner of Public Works, there is a good deal of information of importance to the public; and, as the furnishing of large cities with an abundant quantity of pure and wholesome water can never be a subject of indifference to the medical profession, perhaps it may be well to devote a little space to some of the details mentioned. The area of land which drains into the Croton River above the Croton dam, which supplies the water to this city, is about three hundred and forty square miles, which, according to the record of rainfall, will give an average daily supply of water from rain alone throughout the year of three hundred million gallons. A gauge for many years of the daily quantity of water flowing over the Croton dam, in addition to that which is conveyed into the city by the aqueduct, shows for the past ten years an average daily waste of water of three hundred and forty million gallons.

It is thus manifest that many of the large springs within the Croton basin receive their supply from sources outside of the water-shed, and that a much larger supply can be relied upon, if properly stored, than is shown by calculations from the average rainfall. The Croton Lake (the sedimentary basin of the water-supply), at the head of the aqueduct leading to this city, covers about four hundred acres, and has a storage-capacity (above a level that will allow the delivery daily of 35,000,000 gallons) of about 500,000,000 gallons; the new reservoir in Central Park, 1,000,000,000 gallons; the old reservoir in Central Park, 150,000,000 gallons; distributing reservoir in Fifth Avenue, 20,000,000 gallons: total, 1,670,000,000 gallons. Yet on the 2d of October, 1869, all of this available storage-supply was practically exhausted, and the only supply was an amount not exceeding 27,000 gallons per day, then running in the Croton River. But for the early partial closing of the valves at the reservoirs and in the city, the higher parts of New York would have been entirely without water, and the lower parts scantily supplied.

In Putnam County, at or near the sources of many of the tributaries of the river, are natural lakes, generally of great depth, the waters of which, coming from springs within their basins or near by, are remarkably pure and limpid. These afforded the only immediate means of obtaining a full and adequate supply of water for the city, and in 1870 the right to draw from a number of them was secured, and the outlets cut down.

Thus an ample supply of wholesome water was furnished to the city during the long drought of 1870, notwithstanding it was much more severe than in 1869. It is manifest that if the rains were frequent and evenly distributed throughout the year, there would be a large and constant supply of water; but the long droughts of summer and autumn, and, occasionally, the severe cold of winter, so reduce the quantity running in the river as to make it inadequate to supply the daily needs of the city.

Necessity has therefore compelled the resort to storage-reservoirs, the system of which had been commenced at Boyd's Corner as early as 1866, these reservoirs being filled during the wet season and drawn from during the dry season. The lakes, the waters of which are available in case of necessity, are Glenida, Gilead, Mahopac, Kirk, Barrett, and China, furnishing a total supply of 2,006,000,000 gallons.

Artificial Reservoirs.—Reservoir at Boyd's Corner (finished), 2,700,000,000 gallons; new reservoir on middle branch of Croton River (unfinished), 4,000,000,000 gallons.

In 1869, careful husbanding of the water in the city reservoirs alone saved a large part of the city from water famine.

In 1870, prudent forethought saved the city from stint and secured an abundant supply from the natural lakes and ponds.

In 1873, over one-thirteenth of the year's supply was drawn from three of the lakes and from Boyd's Corner Reservoir, and this draught was during the dry season, and when the daily consumption was 100,000,000 gallons.

In 1874, with a daily consumption of 102,000,000 gallons, one lake and Boyd's Corner Reservoir supplied one-nineteenth of the year's consumption.

In 1875, up to June 5, the daily consumption has averaged 107,000,000 gallons. At that date the Croton Lake was unusually low, and the reserve supply was running into it.

The daily consumption of water has been steadily increasing, year by year, as follows: Average daily consumption in 1870, 85,000,000 gallons; average daily consumption in 1871, 87,000,000; average daily consumption in 1872, 90,000,000; average daily consumption in 1873, 100,000,000; average daily consumption in 1874, 102,000,000; average for five months of 1875, 107,000,000.

The aqueduct is now used very nearly to its full capacity, and with the growth of the city, and the increased facilities for distributing water at higher elevations, the rate of consumption and waste will, no doubt, be proportionally greater each year, and soon the demand for water will exceed the capacity of the present aqueduct to deliver, and the city will be stinted in supply.

A year with the drought that occurred in 1870, with the consumption of the present time, would require a storage-capacity of 4,023,200,000 gallons.

The Chief Engineer very justly says that "it is evi-

dent that, in spite of all the restrictions that can be brought to bear against the waste of water, it will be necessary to build an additional aqueduct from Croton River to Harlem River. An abundance of water for the city's wants for many years to come can be had in the Croton Valley by establishing storage-reservoirs, for which the Croton and its branches offer many admirable sites.

"But to increase the supply of water to any considerable extent involves the construction of a new aqueduct, and I think no time should be lost in obtaining all the requisite data to locate it."

The excursions of the new floating hospital of St. John's Guild have been continued with great success; though, as the average expenses of each trip are about two hundred and fifty dollars, and they are made three times a week, it is a pretty severe drain on the treasury. About a thousand mothers and children go on every excursion, and both breakfast and dinner are always served on board. Some idea of the quantity of food consumed on these excursions may be obtained from the following list of the principal articles used on one of the ordinary trips: 611 pounds of beef, 250 loaves of bread, 3 barrels of crackers, 350 quarts of milk, 1 tub of butter, $1\frac{1}{2}$ barrels of boiled rice, $\frac{1}{2}$ barrel of sugar, 80 gallons of beef soup, and $\frac{1}{4}$ chest of Oolong tea.

Another excellent summer institution is the "Poor Children's Seaside Home," at Bath, Long Island. This has been provided by the Children's Aid Society for the pupils of the industrial schools under their care, and the location is unsurpassed for pleasant surroundings, invigorating sea air, and safe bathing-grounds. Over two hundred children are at the home every week, and it is hoped that two thousand will be able to enjoy its benefits before the season is ended. This pleasant place is only four miles from Brooklyn, and is very accessible both by cars and boat.

PERTINAX.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF NEW YORK.

STATED MEETING, MARCH 10, 1875.

DR. JANEWAY presented a specimen of *urethral calculus* from a boy four years of age. The doctor stated that when called in to see the child he found him suffering much pain from suppression of urine; not a drop had passed for two days. The bladder consequently was greatly enlarged. On opening the meatus, he noticed lodged in the urethra a small calculus, which he succeeded in extracting. The calculus was egg-shaped, three-quarters of an inch long, one-quarter inch thick, and composed of uric acid.

The doctor also presented specimens of bone obtained from the dissecting-room. The first was an impacted fracture of the neck of the femur, showing the new growth of bone around the shaft.

The second specimen was an ankylosed knee-joint, which illustrated very well the disease of bony ankylosis at the knee. The third specimen was taken from a woman aged 35, and was characterized by growths of exostosis. All of her bones were similarly affected.

Dr. MASON showed a specimen of *fracture at the base of the skull*, which was taken from a man aged 30. On admission to the Bellevue Hospital in December last, he presented the appearance of one seriously intoxicated. His breathing for a short time was stertorous. No marks of injury were found. A small clot of blood was found in the ears, but no other fluid was discharged from them. The night he came into the hospital he vomited, and three days after admission he vomited again; the matter vomited each time smelling strongly of alcohol. Five days after admission there was no material change in his condition, except that he appeared to be growing weaker, and complained of some pain in his head. On the sixth day after admission the patient became quite delirious. On the eighth day pupil of left eye more dilated than the right; both, however, responded to light. Some paralysis of left side was inferred from the fact that he could not grasp so strongly with left hand. At this time pulse 104, temperature 101°, respiration 20. On the following day, ninth after admission, all his symptoms much improved, but on the next day he for the first time gave evidence of what his real condition was by a watery discharge from his ears. Diagnosis was then made that the patient probably had fracture of the base of the skull.

On the twelfth day he became comatose, and began to pass his fæces and urine involuntarily. He died on the sixteenth day after admission.

At the autopsy, twenty-four hours after death, on removing the skull-cap, the dura mater was found adherent to the bone, and the sinuses greatly distended with blood. In the middle lobe of the cerebrum on the left side there was a spot of softening two and a half inches in diameter and one inch in depth. On removing the brain an extensive fracture was noticed through the temporal and ethmoid bones.

The point of interest in this case is that the patient with such an extensive fracture in such a situation should present no symptoms of his real condition until at least ten days had passed after the injury was received.

Dr. KIPP presented a specimen of *cancerous disease of the petrous portion of the temporal bone*, taken from a woman aged 47. The specimen was referred to the microscopic committee, to be examined.

Dr. J. LEWIS SMITH said he was called, on February 27, to see a baby, at that time seven days old, which had been sick since the day previous. The family lived in a dilapidated tenement-house in the suburbs of the city. There was no difficulty in determining the nature of the disease. The child had tetanus neonatorum fully developed. A year previously, this family, then living in the same apartments, lost a child from the same disease. The only thing observed unusual in the case up to the time of tetanic symptoms was the existence of a diarrhoea, which the child had had since two days old. At the time of the doctor's visit, the spasms were occurring about every two minutes. Pulse 164, temperature 100½°, respiration 60. During the spasms the muscular rigidity was so great that the body could be lifted up by placing one hand under the child's head and the other under its heels.

The doctor then described the post-mortem appearances, thirty-seven hours after death, the most remarkable of which were the hyperæmic condition of the liver and the brownish discoloration of the surface of the abdomen, showing the existence of *icterus neonatorum*.

BULLET-WOUND OF THE STOMACH AND KIDNEY (*Boston Medical and Surgical Journal*, August 5, 1875).

—Dr. M. E. JONES reports a case of bullet-wound of the stomach and kidney followed by hæmatemesis and hæmaturia. Morphia and gallic acid were employed, and the patient made a good recovery.

SELECTIONS.

A RAPID METHOD OF ASSAY FOR CINCHONA-BARKS.—M. Urbelin, a pharmacist of Nantes, proposes the following rapid method of assay for cinchona-barks: 10 grammes of bark reduced to a coarse powder are moistened with about 30 grammes of water of ammonia; after stirring the mixture to facilitate the penetration of the ammonia into the pores of the bark, about 30 grammes of benzole are poured upon the pasty mass. The mixture is agitated, and after a few minutes the benzole is decanted into a flask, holding about 200 c.c. This operation is renewed four or five times, or until the quinia is completely removed. Into the benzole are poured about 50 grammes of water, containing 2.5 grammes of sulphuric acid; after agitation for a few minutes, the quinia passes from its solution in the benzole into the acid, where it exists as sulphate. The acid liquid is removed from the benzole by decantation, and to it is added a quantity of ammonia-water sufficient to precipitate the quinia, which is separated by filtration, and weighed, after being carefully dried.—*The Laboratory*.

MENINGEAL SYMPTOMS PRODUCED BY QUINIA (*The Clinic*, July 31, 1875).—Dr. Cleveland relates that he was called to attend a case of remittent fever in a boy 14 years of age. He treated it in the usual manner, but, the fever persisting, increased the amount of quinia until he gave four-grain doses. The fever then subsided, but he was shortly afterwards summoned, and found the patient evidently in a state of great cerebral excitement, if not of meningitis. The orbital pains of which the boy had complained had very much increased; the circumscribed pain became a general headache. As it occurred to him that the quinia might have produced the trouble, he discontinued it. The meningeal symptoms subsided in four or five hours. The temperature of the patient had once been as high as 105°, but while in the state mentioned it did not exceed 101°. During the height of the fever the pulse was 120; in the period of cerebral excitement it fell as low as 50 beats per minute. About two scruples had been given, the greater part of it during the twelve hours preceding the development of the meningeal symptoms.

GLEANINGS FROM OUR EXCHANGES.

METASTASIS OF MUMPS TO THE TESTES AND THE BRAIN (*The Boston Medical and Surgical Journal*, June 24, 1875).—Dr. O. B. Shreve reports the case of a young man, æt. 25, who had an attack of mumps, declaring itself by headache, loss of appetite, moderate fever, slight acceleration of the pulse, and swelling of the parotid glands and the tissues in their neighborhood. Two days later he underwent exposure to cold and wet, which was followed by a high fever, with full bounding pulse, furred tongue, pupils dilated, headache, delirium, subsidence of parotid swelling, and turgescence and pain in the testes. In a few days he was perfectly rational, and was much better in every way, the pain and swelling both in the parotid region and in the testes having disappeared. He was, however, suddenly taken with raging delirium which was entirely uncontrollable; pulse 120, face and eyes congested, pupils contracted. These severe attacks were ushered in by a sudden rigidity of all the muscles of the body, and followed by distinct opisthotonos, which was succeeded by violent struggles, during which he attempted to bite, kick, or strike his attendants, and failing in this he gave utterance to the most fearful

shrieks. He became so violent, and was possessed of such great strength, that it became necessary to confine him by a strait-jacket. Bromide and chloral seemed to have no effect on him, although administered in large doses; the pulse became weak, the body was bathed with perspiration, and the patient died comatose.

QUININE AS A GARGLE (*The Practitioner*, August, 1875).—Dr. David J. Brakenridge has for four months treated all suitable cases of sore throat occurring in his practice with a gargle composed of ten grains of sulphate of quinia and five minims of dilute sulphuric acid to each ounce of water. From a considerable experience he draws the following conclusions:

Simple non-syphilitic ulcers of the throat under this treatment at once assume a healthier aspect, and heal rapidly. In syphilitic ulcers, the local treatment has always been accompanied by the internal administration of iodide of potassium or some other constitutional remedy; but the cure was apparently hastened by the quinine gargle. Its effect on the sore throat of scarlatina is very marked, the pultaceous secretion being checked and the inflammatory swelling diminished.

It is of comparatively little use in the early stage of cynanche tonsillar, over which tincture of aconite, in minim doses frequently repeated, has so decided a control. When, however, abscess followed by abundant discharge of pus results, its beneficial influence in checking the suppuration and promoting healing is marked.

In the slighter forms of diphtheritic sore throat it answers admirably, preventing the extension of the disease and promoting the separation of the membranous exudation.

Dr. Brakenridge reports a very severe case of true diphtheria in which the gargle had a remarkably beneficial effect, and says that it is in such cases that he hopes it will prove most useful.

GELSEMINUM SEMPERVIRENS IN ODONTALGIA (*The Practitioner*, August, 1875).—Dr. James Sawyer has rarely found gelseminum fail to give decided and lasting relief in cases of neuralgic pains in the face and jaws associated with carious teeth. He usually gives every six hours fifteen minims of a tincture made in the following manner: Take of gelsemia root, in coarse powder, two ounces; of rectified spirit, twenty fluid-ounces. Moisten the powdered root with ten ounces of the spirit, and allow the mixture to stand for twenty-four hours. At the end of that time pack in a percolator, and add the remaining ten ounces of spirit. When the fluid has ceased to flow, remove the contents of the percolator and press them. Add the pressed liquid to that obtained by percolation, filter, and make up with rectified spirit to a pint. Eleven minims are equal to one grain of the root. There is only a trace of tannin in the tincture, which may be given with any of the preparations of iron.

TREATMENT OF VAGINISM (*The Practitioner*, August, 1875).—M. Bouchut observes that the spasm of the vaginal sphincter in this affection is often due to the same cause as the spasm of the anal sphincter,—a very small, painful, longitudinal fissure being detectable at the lower part of the orifice of the vagina. Forced dilatation would seem to be indicated here as in the fissure of the anus; but before having recourse in either disease to so painful a procedure, we should try simple measures, which will often prove efficacious. To this end M. Bouchut strongly recommends vaginal suppositories, formed of five parts of cacao-butter and three parts of extract of rhatany, thoroughly well incorporated. One of these is to be introduced into the vagina

night and morning, and allowed to dissolve; then a bran-bath should also be employed for an hour daily.

DAMIANA (*Pacific Medical and Surgical Journal*, July, 1875).—Dr. Charles M'Questin, having used damiana extensively in Mexico, where it is employed as a domestic medicine, bears testimony to its efficacy in cases of sexual debility or lethargy of the sexual organs. In such cases the results are all that could be desired. The leaves only of the plant are used. An infusion is made of one ounce of the dried leaves to a pint of water, and this amount is given daily. In a few days the effects are manifest. The infusion has an agreeable aromatic and slightly bitter taste. He is not prepared to state if its properties are those of an aromatic or stimulating tonic, but says that of its aphrodisiac power there can be no question.

APHASIA (*The Chicago Medical Journal*, August, 1875).—Dr. Walter Hay reports a case of aphasia following a blow upon the bridge of the nose,—the immediate sequelæ of the blow, coma and paralysis, having entirely disappeared, but the aphasic condition persisting to such an extent that his speech is limited to one word, "yes," which he articulates distinctly, but in a whisper. His general health is excellent.

In another case, the attack seemed to follow embolism of the left middle cerebral artery, from rheumatic endocarditis, the most remarkable feature being the total and instantaneous obliteration from memory of certain items of acquired knowledge previously in constant use.

CARBOLIC ACID AS A LOCAL ANÆSTHETIC (*Atlanta Medical and Surgical Journal*, July, 1875).—Dr. Eugene Foster asserts, from experience in its use, that carbolic acid is almost worthless as a local anæsthetic; that if complete anæsthesia of a part is obtained, death of the tissues to the extent of the depth of the anæsthesia almost invariably follows; that it is by no means certain to produce anæsthesia, but that it is merely an experiment in each instance in which it is used; that cicatrization of the incision is greatly retarded by the acid; and that in comparison with the ice and salt mixture, ether, or chloroform, as a local anæsthetic, it sinks into utter insignificance.

INCISION OF THE LOWER LID IN CERTAIN CASES OF CATARACT (*The Lancet*, July 31).—Mr. Solomon, in a case of cataract where the eye was so deep-set as to interfere with the section of the cornea during the operation of extraction, simply made a perpendicular incision through the substance of the lower lid of about three-eighths of an inch in length and one-sixth of an inch from the commissure. The front of the eye was now easy of access, and the operation was performed. The tarsal wound was entirely healed on the fourteenth day.

XANTHIUM STRUMARIUM (*The American Medical Journal*, July, 1875).—Dr. William Fulton reports the xanthium strumarium, or common cockle-bur, as one of the most reliable of diuretics. He has found it a specific in all cases of urinary difficulties in pregnancy, and prescribes it in all cases where there is scalding in urinating. He uses it in the form of a tea, or as a saturated tincture, of which he adds about two drachms to a tumbler of water, and gives one tablespoonful every two or three hours.

NECROMETER.—Bouchut found by examination of 1100 men (living, dead, and in a trance) that no corpse has a higher temperature than 20° Cent. (68° Fahr.). He constructed a thermometer (alcohol) in such a way that the alcohol does not become visible before 20° Cent. has been reached. Even a child will be able to tell whether life be extinct or not.—*Am. Jour. Phar.*, July, 1875; from *Arch. f. Pharm.*, May, 1875.

CAUSE OF URETHRAL STRICTURE (*New York Medical Journal*, August, 1875).—M. Oudenhoven, chief health officer of the Dutch marine, has observed that among the Japanese, Malays, and Chinese strictures are very rare, notwithstanding the frequency of blennorrhagia, and he attributes this fact to their peculiar form of dress, which necessitates the performance of micturition in the sitting posture, a position which diminishes the curve of the urethra and frees the genitals and urethral canal from all compression. Among Europeans, on the contrary, the pantaloons cause an augmentation of the curvature and a compression of the canal; micturition, therefore, requires more effort, and the urine produces more friction of the urethral walls; the epithelium is eroded, the inflammation is deeper, and granulation-tissue forms. Oudenhoven, therefore, recommends that all patients with urethritis should be advised to urinate while in the sitting posture.

MISCELLANY.

HOMŒOPATHIC HOSPITAL.—It is reported in the daily papers that the Commissioners of Public Charities and Correction voted, on the 7th [ult.], to place the building heretofore used as an Inebriate Asylum on Ward's Island, under the charge of homœopathic physicians and surgeons, to be used as a general hospital. The following preamble and resolutions were passed accordingly:

"Whereas, More than six months ago an appeal was made to the Board by six hundred and fifty-five citizens and tax-payers to designate an hospital to be under the care of homœopathic physicians; and,

"Whereas, The resolution of this Board, passed February 13, conditionally assigning the Riverside Hospital for the purpose, has proved inoperative by reason of the continued occupancy of that building by the Board of Health; therefore,

"Resolved, That that portion of the Inebriate Asylum on Ward's Island made vacant by the distribution of the soldiers to national homes be set apart for a hospital, to be under the care of homœopathic physicians, under such rules and regulations as the Commissioners of Public Charities and Correction may establish.

"Resolved, That the Committee of the Homœopathic Society, whose petition in this behalf bears date July 3, 1875, and was followed by a personal interview with the Commissioners on the 13th of July, be notified of this action of the Board, and requested to make such suggestions and recommendations as may seem to them calculated to promote the object in view."—*The Medical Record*.

SAD AFFLICTION.—A London physician has a case without precedent, the cause of which he is unable to discover, and which baffles all his skill. Naturally he writes to the *Lancet* about it. The case is this, as he states it:

"Mrs. J——, aged thirty-five, with a large family, suffers from a spasmodic affection of the lower jaw. It will, without any warning whatever, become fixed, so that with all my strength I could not open it. The hus-

band is the only one who can do so; and I have seen him perspire before he succeeded."

The physician says he has tried everything he can think of, both internally and externally, but all in vain. It is a very remarkable case; one of the most remarkable we ever heard of. There have been cases, we are told, quite the reverse of this, as, for instance, when a woman "with a large family" has "a spasmodic affection of the lower jaw," which, "without any warning whatever," becomes unfixed and vibratory, so that the strength of the whole family cannot shut it or stop it, and even the husband, perspire he never so freely, is compelled to flee before it. We do not, of course, profess to be able to prescribe for the London patient, but would it not be possible to make a "swap" of the two spasmodic affections? There are, no doubt, many men who would be willing to exchange the spasmodic affection which unfixes the wife's lower jaw for Mrs. J.'s disease, which fixes it. Doubtless, too, there are husbands who, if their wives were overtaken by a spasmodic affection fixing the lower jaw so that it could not be opened without perspiration, would never sweat again. —*Druggist's Journal*.

In a letter dated Vienna, July 24, 1875, the writer speaks as follows of a recent operation for ovariectomy:

"Billroth's last case, operated on just a week ago, was one of the most difficult and most unpleasant an operator could well meet, the adhesions being far greater than had been anticipated. Omentum, intestines, ovaries, and uterus were so bound together that a great part of the peritoneum was torn away in efforts made to disengage the tumor, which proved to be a multilocular cyst. The adhesions in the pelvis were so numerous that the uterus could not be found, and no drainage-tube could be used to any advantage. The tumor appeared to be nourished not through any distinct pedicle, but through its numerous adhesions, which gave rise to a hemorrhage which was very difficult to control. It was finally stopped by numerous ligatures, all of which were left in the abdominal cavity. As might be supposed, the patient died—in forty-eight hours."

A PHYSICIAN'S certificate, lately presented to an agent of the Southern Express Company, with a corpse for transportation, read as follows:

"I hereby certify that this corps, a daughter of —, died of croup. ———, M.D.

"MAY 10, 1875."

If this physician cannot write Latin better than he can write English, we shouldn't like to take a mixture compounded from any prescription of his.—*The Sanitarian*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM AUGUST 24, 1875, TO AUGUST 30, 1875, INCLUSIVE.

HALL, J. D., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Brown, to comply with par. 3, S. O. 135, c. s., War Department. S. O. 146, c. s., Department of Dakota.

BROWN, P. R., ASSISTANT-SURGEON.—Assigned to duty at Fort Shaw, M. T. S. O. 146, c. s., Department of Dakota.

SATURDAY, SEPTEMBER 11, 1875.

ORIGINAL COMMUNICATIONS.

ON MEMBRANOUS CROUP AND ITS TREATMENT.

BY BEDFORD BROWN, M.D.,

Alexandria, Va.

SETTING aside all theories in regard to the specific character of croup as unsustained either by arguments or by facts, those pathological processes combining to complete the disease known as membranous croup comprise, primarily, engorgement; secondarily, inflammation; and, lastly, exudation on the mucous membrane of the larynx and trachea; or, rather, the destruction and sloughing or exfoliation of the involved epithelium, and then the membranous exudation. This process of epithelial exfoliation is truly one of the most important of all those elements entering into the formation of the disease. Without this preliminary arrangement it would not be possible for the last and most important stage—that of exudation—to occur.

Hence, when the destruction and exfoliation of the epithelial coat have taken place, the basement membrane underneath is laid bare; it can no longer secrete mucus, but becomes the theatre of those important actions consisting in the exudation of plastic material from the exposed vessels, which rapidly assumes the form and consistency of membranes.

Not in all, but in a very large proportion of the cases of tonsillitis coming under our observation, in greater or less degree these identical processes occur and may be observed at any time.

In such cases the affected tonsil first becomes engorged, then highly inflamed, then one or more white or gray patches, sometimes larger than a shilling, appear on its surface. These may disappear and reappear several times before resolution. These cases are usually denominated ulcerative, and, at other times, diphtheritic. In reality they are neither, but of a true exudative character with an innocent type of disease. If such exudations were situated in the larynx or trachea, they would then become matters of infinite moment. In tonsillitis of this character, until the inflammatory action subsides, we may observe this membranous exudation, though removed by local applications, return every day. Its removal is usually followed by bleeding.

The same destruction and exfoliation of the epithelial coat occur here as in membranous croup. Thus, while the epithelial coat exists in its perfection with unimpaired functions, there can be no membranous formation. This fact is one of paramount importance in the pathological history of croup and its therapeutic management.

Bearing on this point there is another pathological question of infinite importance. It is whether membranous croup is a simple inflammatory affection, or a specific disease. Universal experience in the profession unites in establishing the opinion that by appropriate treatment the exudation may be

prevented. Hence the conclusion that this form of croup is a simple form of inflammation. Under intense inflammation, the epithelium ceases to perform its function of secreting mucus. There is an utter suspension of action, and consequently a complete absence of all moisture on the epithelial surface. There is no relief of the engorgement and blood-stasis, and this delicate coat sloughs, leaving the basement membrane denuded, with its injected vessels laden with plastic blood, when exudation results. In simple tonsillitis with limited exudation we have ocular demonstration of the fact that this exudation, when left undisturbed, continues to grow in proportion to the area of the destruction of the epithelium, and also of the fact that during a high state of inflammatory action the epithelial coat so destroyed cannot be repaired until resolution begins. Hence the successive crops of exudation in membranous croup, diphtheria, and tonsillitis, while inflammation continues.

It would appear that in all local affections of an exudative character, morbid action must reach a certain point, must pass only through certain stages, and must be surrounded with favorable circumstances, to complete the process of exudation. When this process is interrupted, either the normal secretion of the part affected takes its place, or purulent formation is substituted. Thus, in the case of incised wounds, the adhesive or plastic form of inflammation is often through slight influences converted into the purulent. In serous inflammations, also, the adhesive may be exchanged for the purulent or serous products either by local or by general influences. In membranous croup we desire to convert the plastic form of the inflammatory products into the mucous before exudation has taken place, and, if possible, into the purulent after that has occurred. Thus, if the epithelial cells coating the inflamed surface should be made to pour out their peculiar secretion there can be no plastic exudation, and these delicate bodies are saved from destruction.

Treatment of the Inflammatory Stage.—Whatever agents will cause a free secretion of mucus in this stage of croup, will prove the best means of preventing the last or exudative stage.

Iodide of potassium is unquestionably one of the most prompt and certain stimulants of the mucous secretion in our possession. With this valuable property it combines an alterative power over inflammations of mucous membranes, which gives it peculiar adaptation to the treatment of the inflammatory stages of this affection. The object in using it is to cause the mucous membrane of the bronchial system to pour out its secretions copiously, with a view of saving the epithelial coat from being destroyed, and preventing exudation. So long as the fever and inflammation are active, the cough clear and metallic in character, the voice hoarse, the iodide may be used energetically and freely. This remedy, to be of service in this disease, must be used in heroic doses, repeated at intervals of one or two hours. Time is a precious consideration in the treatment of croup, and to insure success the system

must be saturated with the drug as speedily as possible. The remarkable sedative influence exerted by this preparation over inflammations of the respiratory tract gives it additional value in the treatment of croup. Its sedative power in the turbulent and labored respiration of asthma and emphysema, in dry catarrh, and in kindred affections, is unequalled by that of any other drug for permanent effect. In addition to this, it is especially adapted to the respiratory diseases of childhood. The action of iodide of potassium over the respiratory tract begins with the Schneiderian membrane, and embraces the mucous surface of the mouth, the entire glandular system pertaining to salivation, the pharynx, larynx, trachea, and bronchial membrane. The normal secretions peculiar to all these surfaces are greatly augmented by its agency. Indeed, its remarkable powers as an expectorant are far from being understood or appreciated.

In the inflammatory stages of croup it may be advantageously combined with the bicarbonate and bromide of potassium, and glycerin, which latter has valuable expectorant properties.

The following formula is adapted to a child of five years of age:

R Potass. iodid., ℥ss;
Potass. bicarb., ℥ij;
Potass. bromid., ℥i;
Aqua, ℥ij;
Glycerinæ, ℥i.—M.

Sig.—Dessertspoonful every hour.

Under the free and energetic use of the iodide in these affections, either alone or in the above combination, when the system is fully saturated with the drug the quantity of salivary and mucous secretion poured forth is sometimes astounding. This is true of croupal, tonsillitic, and catarrhal affections. In cases of tonsillitis with intense injection and tension of mucous surface, and attended with great dryness and want of moisture, the iodide will usually stimulate free secretion from the fauces, to the infinite relief of the local affection.

In a considerable proportion of the cases treated by the iodide of potassium in large doses, there was free and copious salivation, but without any of the peculiar inflammation of the salivary glands resulting from the use of mercury.

The following cases are presented as examples of the treatment of croup by this method.

Case I.—A boy of six years had been very hoarse with fever and croupy cough for several days. When visited, he was suffering from intense hoarseness, genuine metallic cough, labored breathing, and restlessness. The tonsils were inflamed, and presented exudation on their surfaces. This patient took four grains of iodide and five grains of bicarbonate of potassium, dissolved in one teaspoonful of glycerin and a tablespoonful of water every two hours. In twelve or fifteen hours the symptoms were all diminished in violence. In twenty-four hours there were copious salivation and free secretion of mucus from the bronchial surface. The exudation on the tonsils soon disappeared, and the patient, after expectorating small portions of membrane, made a rapid recovery.

Case II.—This was a young and very robust boy of three years. After a preliminary hoarse cough, with feverishness for two or three days, the formal attack of croup set in with very alarming symptoms. The same prescription was resorted to in this as in the former case, only in diminished proportion, with similar results.

Treatment of the Exudative Stage.—After exudation has been fully established a different system of treatment becomes necessary.

The tincture of the chloride of iron, combined with the chloride of ammonium and chlorate of potassium, are the only general reliable means in this stage. They act best when dissolved in glycerin and water. Glycerin is always a valuable agent in croup, as it is one of the few articles which invite moisture to the inflamed surface in the form of sero-mucous secretion.

Thus, when the symptoms of orthopnoea become more permanent, and the fever declines without corresponding improvement, this treatment should be instituted vigorously and without delay. The system must be saturated with the remedies as rapidly as possible; consequently they should be given every hour.

The following case is reported as an example of the effects of this treatment.

Case III.—This was a healthy child of fifteen months. When first visited, it had been suffering with a dangerous attack of croup for two days. There was fever, with great acceleration of pulse, entire suppression of cough and voice, with inability to cry. The respiration was painfully labored, with frequent paroxysms of difficult respiration. After a vain trial of the potash treatment, the following prescription was administered every hour:

R Tinct. ferri chlor., ℥i;
Ammonii chloridi, ℥ss;
Potass. chlorat., ℥ij;
Glycerin., ℥ss;
Aqua, ℥iss.—M.

Dose, one teaspoonful.

In connection with stimulants and nourishment, this treatment was continued with favorable results.

The chloride of iron is not given here, as in diphtheria and its kindred diseases, as a corrective of blood-poisoning, but for its remarkable influence over local disease of a diffuse inflammatory character attended with either exudation, effusion, or extravasation. When absorbed into the circulation in sufficient quantity, it exerts a marked influence on the capillary vessels in the remotest part of the system, contracting their calibre, reducing dilatation, correcting engorgement, and arresting exudation.

THE USE OF BATHS IN THE SUMMER-COMPLAINT OF CHILDREN.

BY J. G. THOMAS, M.D.,

Savannah, Georgia.

I HAVE just read with interest a communication in the *Medical Times* of July 17, by Dr. C. G. Comegys, on the use of water in the "summer-complaint" of children when it is accompanied

by fever. In the variety of this disease which he so accurately describes as enterocolitis we perhaps always have more or less fever.

I desire simply to add my humble testimony to what Dr. C. says so far as the treatment by water is concerned; and of course the use of water as here proposed is only auxiliary to other means.

This disease has been almost epidemic with us this summer, and accompanied with more persistent and obstinate fever than I have ever before known it.

The treatment alone by internal means has been very unsatisfactory; in fact, with me it has always been so in a certain percentage of the cases, for the reason that it is oftentimes impossible to get medicines to remain on the stomach.

In the cases coming under my observation the temperature ranged from 101° to 105° ; and it was those of a very high degree of fever that caused me to get in the habit of using what I call the *reduction* treatment by cold water; and I now employ it in all cases of any fever, varying the temperature by the temperature of the patient. Usually by placing a little patient with fever of 102° to 103° or 104° , in water of temperature 70° to 85° for twenty or thirty minutes, the heat will run down to the normal point or below it, and the child will go quietly to sleep, and wake up in an hour or two, much improved. In families where I have used this for the first time, like Dr. C., I have found it prudent to stay for an hour or two and see the treatment properly carried out, for many nurses and mothers will at first be afraid of it, but they will soon get over all this fear when they observe the charming effect it has upon the child. The plan I have pursued is a little different from that described by Dr. C., and I will briefly explain it, for I am persuaded that it is not so much employed as it should be, although it is so simple and so easily practised by any one.

I first take the temperature of the child before it goes in the bath, and then the temperature of the bath, and, as a rule, have the child put into the water at the supposed temperature at which it is in the habit of bathing. But some children are very nervous about going into water: with such as these we should be very deliberate, and should allow them to get accustomed to it. They should be put into water a little above tepid, to which colder water should be gradually added until the temperature is reduced to 75° ; or, when the fever is very hot, and does not yield readily, to 70° . In many cases the child will scream a short time, but if they are properly managed their cries soon cease, and they wake up an hour after they are taken out, much improved; whereas before, they were unable to sleep for the nervous twitchings and threatenings towards convulsions. The child, after it has been in the bath for from twenty minutes to half an hour, should be taken out, the axillary region dried with a soft towel, and its temperature taken. If we find the heat has gone down to the normal degree or a little below, the child should be wrapped in a light woollen blanket and put in its bed, when, as said above, it will almost invariably sleep for some time. But in one hour its temperature should be taken again, and if it has gone up, the same process should

be gone over. Thus I have kept it up in some persistent and severe cases for days, making the child comfortable, and giving time for the effect of other controlling remedies.

In some cases the fever once reduced in this way will not return for four, five, six, or twelve hours, whilst in others it does not return at all; and in all the baths control the heat so as to make the case one of much less gravity, provided they be properly and persistently used.

I have persuaded myself, since the introduction of the clinical thermometer into use, that heat in the blood sometimes causes convulsions, and that there are many cases in scarlatina, for instance, as well as other diseases, which have died from the effect of heat upon the globules of the blood, which we are in the habit of attributing to the effect of poison of the disease. This conclusion of course is founded alone upon clinical observation, without any pathological investigation.

But I only set out to confirm the experience of your contributor, Dr. C., in the use of baths in this very troublesome and fatal complaint of children; and I feel sure that if it is practised early, with the aid of the thermometer, many little innocents may be saved who now find an early grave.

I have also tried the same reduction treatment in a few cases of malarial fever this season in adults; in these it has acted in the same happy way.

There are scattering cases reported in the journals where it has been tried in rheumatism, scarlatina, etc., with high degrees of temperature, in all of which I propose to try it in future, particularly in scarlatina where the eruption does not appear upon the surface as it should, and the temperature of the patient ranges high.

A SECOND CASE OF RUPTURE OF THE INTESTINES, FOLLOWED BY PERITONITIS, AND DEATH IN THIRTY HOURS.

BY G. WINFIELD ZEIGLER, M.D.,

Resident Physician at the Episcopal Hospital.

MICHAEL O., *et.* 65, married, laborer, was admitted into the surgical ward of the Episcopal Hospital about 10 o'clock on the morning of August 9, 1875, presenting the following history and symptoms.

The officer who brought him stated that the injury, which was caused by severe kicks upon the scrotum and lower part of the abdomen by a man with whom he was quarrelling, occurred two hours before admission.

When I first saw him, he was intoxicated, and unable to answer any questions. His thighs were flexed upon his abdomen, and with one hand he supported his scrotum.

He complained of very severe pain. After transferring him to a bed, I could not detect any external marks of violence excepting a contusion upon the lower part of his scrotum. His abdomen was tympanitic, and very painful upon pressure, more particularly upon the lower and right side. The

scrotum was very much swollen and extremely painful. His pulse was full and rapid; respirations hurried and labored; tongue coated, and skin clammy.

His bladder was empty, and an instrument could be passed without difficulty. He stated that his bowels had been moved a short time previous to the reception of the injury.

The treatment which was ordered consisted in the administration of twenty minims of laudanum, the application of cold to the head, and repeated warm mush-poultices to the abdomen, with an evaporating lotion of lead-water and laudanum to the scrotum.

The thighs were flexed by means of pillows placed under the knees. He was very thirsty, for which milk was ordered.

At 1 o'clock his condition had improved somewhat. The pain was less severe, and his mind clearer. He was now ordered three grains of Dover's powder, to be taken every four hours.

At 6 o'clock P.M. his condition was less favorable, as he began to vomit a thin, frothy matter. Lime-water was now added to the milk, which at first allayed the irritability of his stomach.

At 10.30 P.M. the vomiting had increased, and was tainted with bilious matter. He manifested symptoms of approaching delirium tremens, for which he was ordered twenty-five grains of potass. bromid., to be repeated if necessary. This, however, seemed to quiet him, and he slept for short periods.

At 7 o'clock A.M. next morning he was much worse; the vomiting having kept up more or less through the entire night. His abdomen was tense and highly tympanitic, and the swelling about the scrotum largely increased.

At 10 o'clock peritonitis was fairly developed.

At 1 o'clock his condition was growing much lower, when he was ordered five grains of ammon. carb., to be taken every two hours.

About one hour later, upon being called in haste to the patient, I found him dead when I reached the ward. Immediately prior to dissolution, he ejected large quantities of bilious, with some stercoraceous, matter.

The post-mortem was made twenty hours after death. Decomposition had already set in. No external marks of violence could be found except the contusion upon the scrotum observed during life. The scrotum was very much swollen.

The abdomen was very tympanitic and much distended. Upon section, diffuse peritonitis was found.

The cavity was filled with a yellow offensive fluid, mixed with fecal matter.

The intestines were in a high state of congestion, and in the lower third of the ileum there were discovered *two ruptures*, the larger one being about one inch, and the smaller one-fifth of an inch, in length.

The parts of the gut immediately surrounding, to the extent of several inches, were in a gangrenous condition. The other abdominal organs were in a normal state.

The lungs were apparently healthy, the right one being firmly bound down by old pleuritic adhesions.

The heart was enlarged, thin, and very flabby, with slight ossification and thickening of the semilunar valves.

The scrotal cavity was distended with gas; right testicle very much contused, and filled by bloody extravasation. The left testicle was also contused, but not so extensively injured as the right one.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY COLLEGE HOSPITAL, LONDON.

SERVICE OF MR. ERICHSEN.

Reported by JOHN B. ROBERTS, M.D.

EXCISION OF THE TONGUE FOR THE REMOVAL OF CARCINOMATOUS DISEASE.

THIS man, apparently about sixty years of age, comes to the hospital to be treated for cancer of the tongue. The malignant disease, involving the middle and posterior portions of the member, extends farther back on the right side than on the left; and on the former side there exists a deep ulcer, from which hemorrhage has occurred, so copious as to be only arrested by the application of perchloride of iron.

The great pain which the patient suffers, the presence of noxious discharges which come from the seat of disease, and the certainty of the recurrence of hemorrhage until the man sinks exhausted, are good reasons for the performance of excision of the tongue, which will not only render him far more comfortable, but will, in addition, add to the time which he can survive before the disease proves fatal. Furthermore, the submaxillary lymphatic glands show no signs of carcinomatous involvement, which is still another argument in favor of giving the patient the temporary benefit of this severe operation.

The operation shall be done by cutting through the lip and mylo-hyoid space, then sawing through the symphysis of the lower jaw, and removing the tongue from the hyoid bone by means of the galvanic *écraseur*.

The patient is now fully under the anæsthetic effect of the chloroform, and the incision is made in the median line of the lower lip, extending under the chin to the hyoid bone. It is necessary to secure some little arteries before proceeding; but now after they have been tied, and one of the teeth extracted, a narrow saw is applied to the lower jaw, and the bone carefully divided in the middle. The next step is to cleanse the mouth and fauces of blood by means of these pieces of sponge tied on the end of a stick. Then the assistants pull the tongue forwards with a pair of forceps, and hold the mouth widely open in order that the wire of the *écraseur* may be placed as far back as possible and thus encircle the whole mass of disease. The current from a nitric-acid battery of eight small cells is now passed along the platinum wire, which begins to sear its way through the tissues, and which is tightened from time to time until in a few minutes the tongue is entirely separated from its attachments. There is a little bleeding, however, which must be arrested, but this is speedily accomplished by taking a piece of ice in the forceps and holding it against the bleeding points.

By examination, it is found that the growth extended farther back on the right side than was expected, and that it has not been so completely excised as on the left.

No additional operation would be advisable, however, and the edges of the labial wound shall be brought together by ordinary hare-lip sutures.

In the course of a few days the teeth shall be wired in order to hold the sawn surfaces of the bone in apposition, and thus promote the occurrence of a ligamentous union between them, which will be sufficiently strong, since the patient will never masticate any hard substances. Osseous union might be obtained by drilling and wiring the jaw itself, but the operation would be a tedious one for the man to undergo, and would be unnecessary, since ligamentous union will answer all his requirements.

TRANSLATIONS.

PHOSPHORUS-NECROSIS.—Dr. A. Haas has recently written a memoir on this subject, from an abstract of which contained in *Le Mouvement Médical*, July 24, we take the following:

"Necrosis of the maxillary bones from phosphorus was first mentioned by Lorinser, of Vienna, in 1845. Its existence was soon denied; M. Dupasquier, among others, asserting that the symptoms described were due to arsenic. The growth of the match industry soon afforded numerous opportunities for investigation, and the existence of such an affection was soon placed beyond doubt. The method of its production, however, is still a matter of conjecture.

"A peculiar circumstance, and one which is difficult to explain, is that while the regular match-makers are attacked by the disease in all its malignity, yet the workmen employed in the manufacture of phosphorus itself, although their breath may become so saturated as to be luminous, and those occupied with the red or amorphous phosphorus, enjoy entire immunity from the effects of this poison.

"It has been asserted that the acids of phosphorus dissolved by the saliva penetrate the gums, and by contact with the periosteum and the bone afford an opportunity for the production of necrosis. This theory would account for the immunity of those classes of workers in phosphorus above mentioned, who are only exposed to the vapors of phosphuretted hydrogen, and not, as in the case of the match-makers, to the vapors of oxidized phosphorus. This theory of the local action of phosphorus was maintained by Strohl, while Lorinser and others maintained a general toxic effect brought about by exposure to the poison.

"Experiment has shown that the prolonged administration of phosphorus produces thickening of the periosteum, exaggerated formation of compact tissues, and diminution in the medullary spaces. The action of phosphorus on the exposed periosteum gives rise to periostitis.

"It is known that the bones themselves contain a high percentage of phosphorus. It is, therefore, easy to imagine that under the influence of a dyscrasia produced by the absorption of a toxic substance, the economy, losing in part its faculty for selection, assimilates an exaggerated proportion of bony material with which it is saturated. In this way the formation of osteophytes and that peculiar condensation of the bony substance so often observed can be explained, and as a result of this condensation occur obliteration of the nutritive canals and consequent necrosis.

"The theory of general toxic influence will not explain, however, the peculiar preference shown by the poison for the bones of the face. These bones are the first to ossify during fetal life, and are, besides, the best and most actively nourished of the whole body.

"The affection usually begins by periostitis, followed

by the formation of abscesses, and of fistulæ at the bottom of which a black sequestrum is found. Sometimes the disease invades the maxilla alone; at other times it may progress step by step until all the bones of the face, and even those of the cranium, are invaded.

"It is generally agreed that surgical treatment is called for in removing the dead bone; at what period, however, the operation should be performed does not seem to be decided. M. Haas believes that since the special character of this necrosis is propagation, the operative procedure should be instituted at an early date. In support of his ideas, and in illustration of the disease in general, M. Haas gives the notes of a number of cases, and ends his memoir by the following conclusions:

"I. Necrosis of the maxillæ occurs in workmen in match-factories. It is a necrosis of a specific nature, distinguished by its tendency to propagation.

"II. The expectant plan can and ought to be pursued at the beginning of the disease, because it sometimes terminates rapidly and spontaneously by elimination of the necrosed parts. Treatment is generally unavailing.

"III. When the necrosis shows no sign of self-limitation, when the patient is becoming weakened by the excessive and long-continued suppuration, the indication is for partial or entire resection of the maxilla. As a general rule, however, it is better to disarticulate the entire maxilla when any considerable portion is involved, in order to put an effectual stop to the progress of the disease. This operation is justifiable both on account of its slight gravity and the inconsiderable deformity consequent." X.

PALUSTRAL MELANÆMIA CONSIDERED AS A PROOF OF THE MIGRATION OF LEUCOCYTES THROUGH THE WALLS OF THE VESSELS.—Dr. Léon Colin, Professor at the Val-de-Grâce, read the following communication at a recent meeting of the Société de Biologie.

In palustral intoxication there are reckoned as the principal anatomical lesions: 1. On the one hand, a more or less considerable accumulation of pigment in the splenic pulp; 2, on the other hand, pigmentary deposits in different tissues, especially in those which are most closely in contact with the blood, in the vascular sheaths. These deposits are more common and more abundant along the course of the capillaries of small calibre, like those of the brain, in which the melanin granulations are submitted to prolonged stasis due to the obstacles which they themselves cause in the circulation. The pigment thus deposited in the vascular and perivascular tissues is as black as that which is found in the blood and in the spleen. Dr. Colin does not believe these deposits to be the result of transformation *in situ* of hemosin, of the coloring-matter of the red globules. If these deposits did result from such a transformation, intermediate degrees of coloration would be observed in cases examined during the earlier stages of intoxication. Such, however, is not the case. The migration of the pigmentary granules enclosed in the circulatory current appears to take place through the vascular walls; but does this take place by a simple penetration of melanin granules without any vehicle? There exist, according to Colin, active intermediaries in this migration. These are the leucocytes, which, as is known, seize and retain foreign bodies with which they come in contact, and which, thanks to their amoeboid movements, may then penetrate the vascular walls and spread among the tissues. The leucocytes charged with pigment traverse, then, the vascular walls, and when after this passage they themselves disappear in the tissues in order to play their part in nutrition, they abandon the melanin matter with which they had been impregnated in the blood in the neighborhood of the

vascular walls. In a word, this affection proves much more than those experiments in which, by artificially inflaming the walls of the vessels, local migrations of leucocytes are obtained, migrations which are so abundant as to constitute perivascular purulent collections. It proves that the migration of the white globules is accomplished in the normal condition, without alteration of the vascular walls and above all the circulatory arborescence; and there is perceived a proof long looked for, that of the intimate communication of the solid elements of the blood with the various tissues.—*Gaz. Méd. de Paris*, No. 31, 1875. X.

APHASIA.—From an analysis of a recent thesis by A. Legroux, in the *Archives Générales* for July, we extract the following: Aphasia is characterized by the diminution or perversion of the normal faculty of expressing ideas by conventional signs or of comprehending these signs, in spite of the persistence of a certain degree of intelligence, and in spite of the integrity of the nervous and muscular sensory apparatus which serve for the expression or perception of these signs. Aphasia is of variable intensity; it may affect at the same time all the methods of language with a different degree for each of them; more frequently it attacks only one. Patients may be aphasic of speech, of writing, of reading, of gesture, or may be deprived of one of these faculties only. Aphasia is generally complete and sudden; it only exceptionally becomes progressively developed. This accident may have an acute or chronic course, may be permanent or transitory; there are aphasias which last only a few hours or a few days. Such are those of the hysterical, epileptic, or neuralgic. The most frequent cause of this accident is softening of the brain. The seat of the lesions resulting in aphasia is ordinarily in the anterior lobes of the brain, almost always in the left anterior lobe, and sometimes, probably, as a result of some functional anomaly, in the right anterior lobe; most usually the alteration affects the posterior portion of the third frontal convolution on the right side. In those instances of transitory aphasia without paralysis, it has been thought that a simple congestion might cause the perversion of language. X.

ACTION OF IRON ON NUTRITION.—Rabuteau (*Centralblatt f. Chirurgie*; from *Comptes-Rendus*, t. 80, p. 1169) has carried out a series of researches in his own person relative to the effect of iron upon tissue-change.

Each series of experiments extended over fifteen days, during which he took the same sort of nourishment, exercise, etc. During the first five days the daily excretion was exactly determined. From the sixth to the tenth day, then, two grains of chloride of iron were taken daily, the observations being continued, and during the last five days the estimation of iron excreted was included.

It appeared that the amount of urine was unchanged, its acidity was decidedly increased, during the administration of the iron. This fact is sufficient to justify the use of ferruginous preparations in cases of phosphatic urine, lithiasis and oxaluria, and to place in a correct light the favorable results observed from the iron treatment in such cases. The amount of solids and the urea in the urine were increased about ten per cent.; it thus appears that the administration of chloride of iron even in moderate doses increases tissue-change not inconsiderably. Rabuteau alludes to the rise of body temperature observed by Pourowski while taking iron, indicating increased oxidation, which is also indicated by the increase in urea. X.

COMPLETE LUXATION OF THE ASTRAGALUS (*La France Médicale*, August 7, 1875).—Dr. A. Rigal reports the case of a young man who fell in a ditch, the left foot receiving the weight of the body while extended

upon the leg. On the dorsum of the foot, in advance of the malleoli, there was a tumor which was easily recognized as the astragalus, whilst in the place normally occupied by that bone there was a depression very sensitive and painful to the touch. According to the author, the mechanism of this luxation was as follows. In consequence of the weight of the body coming suddenly upon the foot, there was an exaggeration of the normal arch of the latter under the influence of two forces which act normally in reverse directions upon the extremities of the toes and the heels. At the same time there was a twisting of the astragalo-scaphoid articulation, and depression of the articular surfaces, followed by propulsion of the astragalus from behind by the tibio-fibular "mortise" in the exaggerated movement of extension upon the leg. After the rupture of the ligament the astragalus was forced from its cavity like the stone of a cherry pressed between the fingers. In order to effect reduction, an assistant, taking the malleoli as a point of resistance, applied his thumbs vigorously to the head of the astragalus, and endeavored to thrust it downwards and backwards, while M. Rigal carried the foot upwards and outwards. At the second attempt the bone re-entered abruptly, and two months later the patient had entirely recovered.

In ninety-three reported cases of complete luxation of the astragalus, not compound, this was only the twenty-seventh time that reduction had been effected.

J. W. W.

THE POISONOUS PROPERTIES OF A SERIES OF ALCOHOLS (*La France Médicale*, August 4, 1875).—At a recent meeting of the Académie des Sciences, MM. Dujardin-Beaumetz and Audigé reported the results of a series of experiments on some of the alcohols produced by fermentation, including ethylic, propylic, butylic, and amylic alcohol:

1. The toxic properties of this series follow mathematically their atomic composition; whenever the latter is represented by high numbers, the poisonous action is marked, and this is the case whether the alcohol has been introduced through the skin or by the stomach.

2. For the same alcohol, the toxic effect is greater when it has been given by the stomach than when it has been administered through the skin. In the latter case, however, the dilution of the alcohol augments its action.

3. The poisonous phenomena observed appear to be the same in general, except the degree of intensity, whichever alcohol be employed.

The lesions produced also follow an increasing order from ethylic to amylic alcohol. The disturbances of the intestinal mucous membrane are all as intense when the alcohol has been given hypodermically as when it was given by the mouth. With the same alcohol, pulmonary congestion and apoplexy were more frequent when it had been given by the stomach.

J. W. W.

SULPHURIC ETHER IN THE TREATMENT OF STRANGULATED HERNIA (*Bull. Gén. de Thérap.*, July 30, 1875).

—Dr. F. Alessandri has observed six cases of strangulated hernia in which the use of ether was attended with excellent results. The patients were in great pain, nauseated, vomiting, and with complete obstruction of the bowels, the hernias being entirely irreducible. They were given a little ether by inhalation, an injection of a decoction of chamomile containing a few drops of ether was administered, and, at the same time, compresses soaked in ether were applied over the hernia. Following this treatment in each case there was an escape of gas from the bowels, and it was then found possible to reduce the hernia. From these experiences Dr. A. has been led to administer etherized injections in the meteorism of typhoid fever, and with very excellent results.

J. W. W.

ESCAPE OF PERITONEAL EXUDATION AT THE UMBILICUS (Baizeau: *Arch. Gén. de Méd.*, 1875).—Baizeau has observed two cases of recovery from purulent peritonitis in which there was spontaneous escape of pus at the navel, one of which is particularly remarkable owing to its long duration and the many serious complications by which it was attended. The patient was a boy aged 12 years, who was attacked with peritonitis in February, 1868, and in the course of his illness suffered also from pleuro-pneumonia, suppurative pleurisy, and parotitis also going on to suppuration. The pus in the abdomen found a way for itself to the navel, and the wound at this point was kept open by drainage-tubes, while the abdominal cavity itself was washed out twice daily with tincture of iodine largely diluted. The thorax was opened with a bistoury, and the pleuritic exudation treated in the same way as the abdominal. The drainage-tube was removed from the thorax on the 1st of October, from the navel on the 20th of December, and the boy finally made a complete recovery.

The second case was that of a girl aged 10 years, was uncomplicated, and received similar treatment, which was followed by cure at the end of three months. B. attributes great importance to the use of drainage and the injection of the dilute iodine. W. A.

THE INFLUENCES OF DIFFERENT MODES OF ANTI-SYPHILITIC TREATMENT ON PREGNANCY (F. Weber; *Allg. Med. Centralztg.*, 1875, Nos. 10 and 11).—These observations were made upon one hundred and twenty-nine pregnant women, among whom it should be noted that twenty suffered from gonorrhœa with slight complications. In twenty per cent. pregnancy did not continue until full term, the time at which it was interrupted being, in a large proportion of the cases, in the seventh or eighth month. Most of the children of these women died soon after delivery. The most favorable results were attained by the treatment by mercurial inunctions, for of the women thus treated, thirty-five in number, none aborted. Of twenty-three women who were treated by inunction and the iodide of potassium, or in whom, owing to debility, inunction was substituted by the iodide, twenty per cent. aborted. When the iodide of potassium and the bichloride of mercury were used there were fifteen per cent. of premature deliveries; and when the iodide alone, thirty-six per cent. After delivery the condition of the women who had been treated by inunction was more favorable than that of those on whom other modes of treatment had been carried out. W. A.

TREATMENT OF EPILEPSY AND OF CHILDREN'S CONVULSIONS (*Bull. Gén. de Thérap.*, July 30, 1875).—In a certain number of cases of epilepsy and eclampsia, the origin of the attack seems to be an instantaneous vascular contraction, propagated from the periphery towards the centre. Following this idea, Dr. Demme gives a hypodermic injection of from one to two milligrammes of atropia. In a case of obstinate convulsions occurring repeatedly in a child of six months, he obtained marked amelioration by injecting a solution containing five milligrammes of atropia to one hundred grammes of water. According to him, the effect produced depends on the paralyzing action which atropia exercises upon the terminal intracardiac branches of the pneumogastric and upon the peripheral vaso-motor nerves. J. W. W.

LUMBAR AND ABDOMINAL NEURALGIA PERSISTING AFTER THE CURE OF UTERINE LESIONS (*La France Médicale*, August 7, 1875).—M. Siredey calls attention to the persistence of the pains caused by uterine and peri-uterine inflammation after the disappearance of these diseased conditions. The painful localities are at

the points of emergence of nerves in the groin, upon the abdomen, in the lumbar region, etc. Instead of attempting to treat the uterus, which has often returned to its normal condition, we should consider such cases as induced by a nervous temperament, and should treat them by hypodermic injections of morphia, cinchona, pills of iron and quinine, and, if the patient is able to support them, by cold douches. J. W. W.

TREATMENT OF ACUTE PERITONITIS BY THE INJECTION OF WATER INTO THE PERITONEAL CAVITY (*Bull. Gén. de Thérap.*, July 30, 1875).—Basing his opinion upon some experiments made upon dogs by Nerlin, and also upon the practice of ovariologists, M. Netter thinks that injections of water might be of service not only in ordinary peritonitis, but also in the puerperal variety. He believes that aqueous injections into the abdominal cavity, employed from the onset, may cut short acute peritonitis, and that we would now be justified in making such injections at least in all cases of traumatic peritonitis when at the same time there exists a wound, made either accidentally or surgically, and permitting the introduction of a canula. J. W. W.

RUPTURE OF AN HYDATID CYST INTO THE VERTEBRAL CANAL; COMPRESSION OF THE SPINAL CORD (*Gaz. Heb.*, July 23; from *Bull. de la Soc. Anat. de Paris*, 1875, p. 93, t. lx.).—The patient, without previous symptoms, suddenly became paralyzed on rising from his bed one morning. The paralysis continued, bed-sores and urinary troubles supervened, followed by death. The autopsy showed an hydatid cyst, opening into the vertebral canal on a level with the ninth and tenth dorsal vertebræ, and which compressed the cord. The cyst was found to have originated in the right pleural walls, and to have penetrated the intervertebral disk. X.

ON THE ORIGIN OF VESICAL CALCULI (Franz Hofmann: *Archiv der Heilkunde*, 1874).—Calculi from the bladder of the ram are characterized by great softness, and when fresh were found to contain 86.84 per cent. of water, leaving only 13.11 per cent. of solid matters. After having been dried, they floated when thrown into water. After treatment with acetic acid a framework was left, which was found, upon examination, to consist of spermatozooids, so that in explanation of their origin it must be supposed that the seminal secretion found its way into the bladder, and became thickened by the precipitation of urinary salts upon it. W. A.

PAIN ABOUT THE KNEE IN COXALGIA.—A. E. Fick (*Wiener Med. Wochens.*, 1875, No. 10) endeavors to prove that many persons who have no anatomical knowledge, more especially children, have no idea of the existence of a joint at the hip, and refer all the action of locomotion to the knee. Since the power of localizing sensations in the interior of the body is but slight, the pains attending commencing coxalgia, which usually are not very severe, are not sufficient to call the attention of the patient to the real seat of the disease. The suffering, however, becomes more and more severe, and is finally connected with movement of the hip. W. A.

TREATMENT OF OZÆNA BY INJECTIONS OF CHLORAL (*Bull. Gén. de Thérap.*, July 30, 1875).—M. Créquy reports the cure of an obstinate case of ozæna by the injection of a solution of chloral. He simply made a siphon of an india-rubber tube by putting one end to the injection and the other well up into the nasal cavity. The disease had resisted injections of tannin, phenol, corrosive sublimate, etc., but was cured in a short time by this method. J. W. W.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 11, 1875.

EDITORIAL.

GLASS.

OUR readers have no doubt heard of the discoveries which threaten to break the uniformity of processes and results that has reigned supreme in glass-manufacture since at least 1500 B.C., when was prepared that bead which a modern explorer unearthed in Thebes. The particulars of these discoveries are not so widely known, and merit mention here. The discoverer of "toughened glass," M. de la Bastie, is not a glass-manufacturer, but is a French gentleman, educated as an engineer, but placed by his private fortune beyond any need of practising his profession. For many years he has devoted himself to his self-imposed task, and finally, knowing that the toughness and tenacity of steel are greatly increased by dipping hot plates of it into heated oil, tried a similar method upon glass. Somewhat over two years ago he succeeded in producing glass which would bear hammering; but, with various articles of such character staring him in the face, he found that he had lost the key and was unable to duplicate his work.

It required two years of unwearying industry before complete success was at last obtained, but then an inexpensive glass was produced which bids fair to change the old proverb, "as brittle as glass," into "as tough as glass." The bath now used is a mixture of oils, tallow, wax, and resin, and similar substances, and the hotter the glass is when plunged into it the better is the result. A thin plate of this thoroughly toughened glass let fall on an iron

grating rebounded a foot without injury. The new material cannot be cut with a diamond, but yields readily to the emery-wheel. Consequently, whilst for window-panes it will probably be necessary to use only set sizes, unbreakable cut-glass utensils are readily prepared of any shape or size. Already this toughened glass has been introduced into the English market, and preparations are being rapidly perfected for manufacturing it on the largest scale. Curiously enough, whilst M. Bastie was perfecting his process, another civil engineer, Mr. Macintosh, of Westminster, was experimenting upon the hardening of glass. Like M. Bastie, he also drew his inspiration from the iron-workers, among whom he indeed has been prominent. Like Bastie, he practised the plunging of heated glass into baths, but by having the liquid at a very low temperature he succeeded in rendering glass, clear or colored, as hard as the hardest gems. He asserts that he has made fictitious gems even harder than real diamonds.

The results obtained by these two experimenters seem to show that glass, like steel, may be tempered at will, and suggest an almost limitless train of useful applications.

SPOONS IN MEDICINE.

THE following award of a coroner's jury in the city of Exeter, England, speaks for itself. The use of the minim-glass or of the drop is the proper way to administer powerful remedies. If the spoon be used, the physician should always ask to see the spoon which is to be employed:

"Congestion of the lungs, accelerated by an overdose of opium innocently administered by her mother from a *modern* teaspoon, containing two drachms, instead of from a teaspoon of older date, containing one drachm."

The victim was an infant.

SOME of the Western journals are occupied with the discussion of the action of the Evansville Medical Society, which expelled a member for announcing himself as a specialist through the daily press. There can be no doubt that the Society was right: its quondam member was certainly guilty of that which is said to be worse than a crime,—a blunder,—and should suffer accordingly. The correct interpretation of the code of ethics, according to the tolerated practices of some of the leading Eastern specialists, is to open a dispensary, under the ægis of some established institution if possible, otherwise in a hired room around the corner from the office, and advertise this special dispensary,

adding, in displayed type, Dr. —, aurist, or what may be, in charge, office such and such street, hours such and such. Then all goes merry as a marriage-bell; the dear public learn where their special ills may be cured, practice flows in, professional etiquette is maintained, and universal harmony prevails.

URINALS.—Whether, by locating proper urinals, our city authorities will ever do away with the hideous sign-boards “Commit no Nuisance here,” as well as with the stained walls of alley-ways and the streamlets which trickle often most inopportunistically in the evening across the pavements, we do not know. We live, however, in hope, and consequently note with interest that in London only such urinals are found to remain decent as are built of slate, with a wide, well-inclined gutter, and a free stream of water constantly running.

THE lowest point in the race towards complete degradation appears to have been reached by the Keokuk Medical College. According to the *Clinic*, its catalogue is illustrated with a “hideous dissecting-room scene.” The pictures displaying perineal dissection are said to be “disgusting in the extreme.” *O tempora! O mores!*

OUR readers will remember our notice of the case of Dr. Wood, who was put on trial in England for manslaughter, on account of the death of a woman under his care from rupture of the uterus during labor. We are happy to say that, by direction of the judge, he has been acquitted.

THE London *Lancet* warns against the deleterious effects of travel in the underground railways of the metropolis, on account of the excessive impurity of the confined air of the tunnels.

THE Philadelphia colleges have already commenced their autumnal courses, and the indications of large classes this winter are very good.

LEADING ARTICLES.

THE INFLUENCE OF THE LOWER ORGANISMS IN THE PRODUCTION OF INFECTIOUS AND CONTAGIOUS DISEASES.

III.

IN addition to the diseases which are connected with the putrefactive process or with local inflammations, bacteria have been found in all fevers, the contagious characters of which have been by some attributed to these organisms.

So far back as 1850, Panum expressed the idea that the development of a certain kind of fungus stood in a specific relation to cholera. More recently Coze and Feltz have maintained fevers to be, in fact, internal fermentations, depending upon organisms in the blood. Hallier regards them as internal parasitic diseases, and attempts to describe the various forms of fungi observed in each. Buhl, Waldeyer, and Wagner describe a disease under the name of *intestinal mycosis*, which they suppose to be intimately connected with malignant pustule, and which proves most rapidly fatal with choleraic symptoms.

As regards the bacteritic origin of malignant pustule itself, reference has already been made to this point. Bollinger thinks, with the authors just mentioned, that the so-called intestinal mycosis is only a form of malignant pustule. Christot and Kiener found bacteria in the blood of a man who died of glanders, and also in the blood of various inoculated animals. Although Obermeier does not attempt to decide whether the moving filaments he describes as occurring in recurrent fever are specific or even at all pathological, the discovery of their constant presence in this disease must be most interesting as bearing upon the present question of animated pathology. The various substances found by Salisbury in the excreta of different diseases seem unlike anything met with by other observers.

Bacteria, as we see them, are described as occurring in a large number of diseases of the most varied nature, differing not only very widely in their clinical history, but which have also for many centuries held places in very separate categories. How far may each of these diseases, so radically distinct in their natures, be attributed to a specific organism peculiar to itself? Hallier endeavored to answer this question by describing a distinct form of fungus for each fever; his ideas, however, have long since been abandoned. Few other attempts have been made to draw any distinctions between the forms of fungi found in different diseases.

Letzerich has recently described a form of fungus which he finds in the mucus, and even air-vesicles, in whooping-cough. This he considers the specific cause of the disease, and believes himself able to produce true whooping-cough in the rabbit by means of the fungi removed from patients suffering with this disease and cultivated in a solution of sugar! He also describes differences between the diphtheritic fungi and those found in whooping-cough, in their mode of development, appearance, and action: the fungus of the latter disease does not penetrate the tissues or tend to produce putrefaction, both of which characters are found in the diphtheria bacteria. Klein has described some very peculiar organisms in the tissues around the lesion of typhoid fever, which seem unlike the micrococci usually met with and may be peculiar to that disease. Billroth says, and we believe this opinion is now shared by most adherents of the bacterial theory of disease, that though different modes of culture may produce various forms, according to the nutrient matter used, none differ in any essential point from those found in

putrid substances outside the body. From this fact, and from the similarity which exists between the forms described in various diseases, he concludes that, up to the present, no morphological distinction is known by which one can decide that a given bacterium belongs to any definite disease.*

Besides the investigations into the bacterial origin of malignant pustule, glanders, recurrent and typhoid fevers, and whooping-cough, above mentioned, researches into the following affections have of late been undertaken from the same standpoint. Heiberg, Virchow, Eberth, Rud. Maier, Burkhart, Heiler, have all contributed studies or single cases of the so-called endocarditis bacteritica, mycosis endocardii, or diphtheritic endocarditis. Researches upon the bacterial origin of erysipelas have been published by Anfrecht, Orth, Hirschberg, Hiller, and Lukomsky, the latter attracting very considerable attention. In regard to cholera, Lewis's and Cunningham's researches have been very careful and are worthy of study. Eberle, Nedswetzky, and Andreas Högyes have also published researches in the same direction. Variola as connected with the lower organisms has received attention from Lugenbühl, Zuelzer, and Weigert. Even acute yellow atrophy of the liver has been regarded by Klebs and Lander as connected with bacteria.

Recently a discussion took place in the London Pathological Society upon the germ-theory of disease, in which the whole subject was brought up for review. Dr. Charlton Bastian, a well-known advocate of the theory of spontaneous generation, opened the question in an able address combating the hypothesis of a bacterial origin of disease. The propositions maintained by him may be briefly summed up as follows:

1. With two exceptions, no definite germs or organisms are to be met with in the blood of patients suffering from these diseases in any stage of their progress.

2. The virus or contagium of some of these diseases, whatever it may be, does not exhibit the properties of living matter.

3. On the other hand, the virus of most of these contagious diseases with which definite experiment has been made is most potent in the fresh state, whilst its power very distinctly diminishes in intensity as organisms reveal their presence more abundantly therein,—facts which seem to point to the conclusion, or at least are quite consistent with the notion, that the contagious poison may be a chemical compound which gradually becomes destroyed or modified by the successive changes taking place in association with processes of putrefaction.

4. There is the extreme improbability of the supposition that this whole class of diseases should be caused by organisms known only by their effects.

5. The facts of the sudden cessation, periodical visitation, and many other phenomena of epidemics, however difficult they may be to explain upon any

hypothesis, seem to oppose almost insuperable obstacles to the belief that living organisms are the causes of such epidemics of specific contagious diseases.

Dr. Bastian's views were ably attacked by Dr. Burdon Sanderson, who pointed out the impossibility of reconciling the appearance and disappearance of the spirilla germs in the exacerbations and intervals of relapsing fever with any theory of contagion save the germ-theory. He also alluded to the course of sheep-pox, where two processes went on simultaneously, the development of pustules and the development of organisms. The debate was carried on by various other investigators, of less celebrity, but showed a tendency to theorizing without an adequate amount of facts, and, upon the whole, the discussion has not added very much to our knowledge of the subject.

Birch-Hirschfeld, in a general survey of the present state of our knowledge of the bacterial origin of disease, speaks as follows:

"We must confess that in a majority of diseases the fungous origin of which has been made the subject of inquiry, we possess little or no exact proof of a parasitic cause, not even in the case of malignant pustule or that of relapsing fever. But the *probability* that bacteria are not insignificant associates of these pathological processes is, to an unprejudiced observer of the facts recently discovered, very strong, and the same may be said of the diseases previously mentioned.

"The chief difficulty in the discrimination of the objects alluded to lies in their extremely small size, in the unsatisfactory condition of our knowledge regarding their development and the circumstances of their existence.

"The morphological similarity of the various species of bacteria found in connection with different diseases is certainly, as has been said before, no evidence against their pathological significance, but it undoubtedly is a great hindrance to their convincing demonstration.

"There can be no question, however, on the other hand, that much which we already know regarding various circumstances connected with the life and development of bacteria agrees singularly well with the ideas impressed upon our minds when we endeavor to form a conception of the infectious material of epidemic disease. We find ourselves under these circumstances almost inevitably forced to think and speak of the *germs* of infection, not the *gases* of infection, and so on. The usually unnoticed penetration within the body, the period of incubation (which we can scarcely explain otherwise than by the theory that the germs must first develop themselves in the body to a certain extent before they unfold their injurious action), the spread and increase of contagion from sick bodies,—all these facts point to such an explanation.

"Let it be considered, further, that only a portion and not all of the population are attacked in an epidemic of any given disease, although the infectious material undoubtedly reaches all or nearly all. This obliges us to admit that the observed facts are most easily ex-

* We are indebted for this review of progress, as well as for various other materials used in this article, to a "Report on Pathological Anatomy," by Dr. Gerald Yeo, Irish Hospital Gazette, October 1, 1874.

plained if the infectious material is conceded to be of a vegetable organic nature, the germs of which do not flourish under all circumstances, but only where they find an appropriate soil.

"It must be conceded, however, that so far as most of the forms of bacteria are concerned, investigation shows that if they are not received in too overwhelming quantity the *healthy* organism offers them an almost absolute resistance. Proof can be adduced in support of this; besides, there are certain bacteria which are injurious only when their invasion occurs in an already disturbed locality. Proof also is available in the case of many diseases for the assertion that *those only are attacked by the disease who were sick already*."

In concluding this article, which, from the circumstances of the case, is brief and imperfect, and which, from the mass of material to be examined, must necessarily often appear to a certain degree undigested, we must refer the reader desirous of further knowledge of the matter to the articles quoted, and also to a lecture by Moritz Kaposi, published in the *Vierteljahresschrift für Dermatologie und Syphilis*, 1874, p. 55. This article is accompanied by a plate giving admirable representations of the principal varieties of disease-organisms. Dr. Stimson's article, which is perhaps more accessible, is also accompanied by a very good plate.

REVIEWS AND BOOK NOTICES.

ON THE ADMINISTRATION AND VALUE OF PHOSPHORUS.
By E. A. KIRBY, M.D., M.R.C.S., Esq. Philadelphia, Lindsay & Blakiston, 1875.

This pamphlet of over fifty pages is very readable, contains much asseveration and explanation as to the value of phosphorus in various conditions of nervous exhaustion, but puts forth very little that is at once new and valuable. Its *raison-d'être* appears to be the peculiar preparation which its author invented, and which is prepared at the laboratory of H. & T. Kirby & Co.,—this pulula phosphori mollis seemingly affording the only perfect method of exhibiting the drug that ever has been or will be produced by human ingenuity. The subject of the administration of phosphorus is certainly very important, and the desire at the same time of doing good and advancing the fortunes of self or family is no doubt a laudable one, but in therapeutic writing the result is not apt to be especially unbiassed and trustworthy. Therefore we advise our readers to season their reading of the brochure with at least a grain of salt. If the pills really contain the metalloid unoxidized in a diluent favoring solution, they must be good; we suppose they are good. Whether they are better than all other forms of administration is more doubtful; probably they resemble closely the preparation of Prof. Percy, of New York, in which the drug is dissolved in cacao butter and coated with gelatin. After reading the pamphlet, we confess, it still seems to us wisest to eschew all pills of phosphorus, although they have the great advantage of tastelessness, because they are liable to vary in the amount of the remedy contained in them, and to undergo oxidation and deterioration by age. The oleum phosphoratum of the Prussian Pharmacopœia, which has been much used, is undoubtedly very nauseous; but if to a saturated solution of phosphorus in chloroform an equal amount of spirit of camphor be added, and the

whole made into an emulsion with gum, a little sugar, and mint-water, the resultant liquid is usually taken without complaint.

THE MOVEMENTS AND INNERVATION OF THE IRIS. By DR. H. GRADLE. Chicago. Pamphlet, pp. 56.

This brochure is a reprint from the *Chicago Journal of Nervous and Mental Disease*. It is a brief *résumé* of the results obtained by numerous experimenters on the physiology of the iris, and offers a very fair view of our present knowledge of the much vexed subject of which it treats. It is too brief to be satisfactory to the general reader; but the very numerous references to authorities make it valuable as a bibliography of the subject. The author has thrown no new light upon points still held in dispute. S. D. R.

SELECTIONS.

CHOLAGOGUES.—In Dr. Rutherford's and M. Vignal's experiments a modification of Röhrig's method was adopted. Dogs which had fasted for eighteen hours were curarized, and artificial respiration maintained. A canula was tied in the common bile-duct; the cystic duct was clamped. The bile flowed from the canula into a finely graduated cubic centimeter measure, and the quantity secreted was recorded every fifteen minutes. It was shown that this method of continuous observation yielded results far more reliable and instructive than that adopted by Röhrig.

Two experiments on the secretion of bile in dogs that had fasted for eighteen hours, and which received nothing more than the doses of curara used in all the experiments for the purpose of keeping the animals at rest, showed that the biliary secretion was not affected by the doses of curara given; that the biliary secretion, on the whole, somewhat diminishes in the course of an experiment lasting from six to eight hours, but that the chemical composition of the bile remains almost exactly the same. The curara was always injected into a vein; the various substances hereafter mentioned were injected directly into the duodenum; for this purpose the wound in the abdominal wall was opened, and the substances injected through the wall of the viscus.

Three experiments with croton oil showed that although it produced violent irritation in the alimentary mucous membrane in all cases, it increased the biliary secretion in only one instance. A high place is, therefore, not assigned to this substance as a stimulant of the liver.

Six experiments with podophyllin proved that this substance greatly increases biliary secretion. A definite statement regarding the composition of the bile before and after podophyllin will be given in the report. Röhrig's statement that aloes deserve a high place as a hepatic stimulant was confirmed by three experiments, in which the extract of Socotrine aloes was employed. The analysis of the bile (not hitherto given), however, showed that after aloes the bile is more watery; nevertheless, the velocity of secretion is so much increased that it certainly causes the liver to excrete more biliary matter.

Three experiments with rhubarb proved that it is a far more important hepatic stimulant than Röhrig has stated it to be. Doses of rhubarb were given nine times in the course of the experiments, and they never failed to excite the liver within half an hour after they were given. Analysis of the bile before and after rhubarb in all the three experiments proved the remarkable fact that, notwithstanding the greatly increased velocity of secretion after rhubarb, the bile-solids secreted by the hepatic cells are not diminished. The rhubarb appar-

ently calls forth an increased secretion of normal bile. Three experiments with senna proved that its power as a cholagogue is far below that of rhubarb. The bile is rendered more watery. Four experiments with the aqueous extract of colchicum proved that it is a very decided cholagogue. The bile was rendered more watery, but the increase in the velocity of secretion was such that the amount of biliary matter excreted by the liver was certainly increased.

Two experiments with the solid extract of taraxacum proved it to be a cholagogue, though not a powerful one. Two experiments with scammony proved that it has a slight cholagogue action. Of four experiments with calomel, the secretion of bile was slightly increased in one, but there was nothing but diminution of the secretion in the other three. Purgative action was produced in all. The bile was rendered more watery.

Two experiments with gamboge gave no evidence that this substance is a cholagogue. One experiment with castor oil confirmed Röhrig's statement that this substance has scarcely any cholagogue power. Two experiments with dilute alcohol injected into the stomach showed that after the alcohol was given, the secretion of bile slightly diminished.

In the report, a full account will be given of the post-mortem examination of the state of the alimentary canal (hitherto entirely omitted in such experiments), so that the effect upon the biliary secretion and that upon the intestinal mucous membrane can be compared.

It was shown that the increased biliary flow from podophyllin, rhubarb, etc., in these experiments could not be ascribed to reflex contraction of the gall-bladder, for this had been previously wellnigh emptied by digital compression, and the cystic duct had been clamped. Nor could it be ascribed to reflex spasm of the larger bile-ducts, for the exaggeration of the biliary flow was far too great and far too prolonged to be explained in this way. Reasons were adduced for regarding it as probable that the agents are absorbed, and act on the liver directly. It was not professed, however, that their *mode of action* was definitely settled, the experiments having had for their primary object a determination of the facts of the case.

The opinion was expressed that powerful purgative action tends to diminish the biliary secretion.

When a hepatic and intestinal stimulant, such as podophyllin, is administered to an animal that is not fasting, it is probable that—1, the liver is excited to secrete more bile; 2, the absorption of bile and food from the small intestine is diminished on account of the purgative effect.

In conclusion, it was pointed out that this research proposed to be simply a contribution to comparative physiological pharmacology; and that it was left to the clinical investigator to compare these results with those observed in human pathological conditions.—*British Medical Journal*.

INJECTION OF QUININE INTO THE TRACHEA IN INTERMITTENT FEVER.—Some years ago, Dr. Jousset, of Bellesme, travelling in the northern part of the Greek Archipelago, was called in the morning to see a Greek child, aged twelve, who was seriously ill. On arriving, he was informed that the child was delicate, and liable to febrile attacks, but had been in her ordinary health the day before, when she had been playing with other children. In the evening she had suddenly become pale and shivery, and the parents thought her dead; but after two hours or less she had partially recovered and fallen into a deep sleep. In the course of the night she had two more fainting-fits. When Dr. Jousset saw her, she was lying on a thin mattress on the floor, extremely pale, with deep-sunken eyes,—in a word, like

death. The respiration was scarcely perceptible; the pulse from 38 to 42, very feeble. Slight indications of intelligence still remained. On auscultation, coarse râles were heard. The belly was soft, the liver normal, the spleen very large. M. Jousset diagnosed it as a case of malarial fever of bad type; and he immediately endeavored to give the patient some quinine, but vomiting was induced, and syncope. Having previously had a successful case, he at once proceeded to inject a solution of hydrochlorate of quinine into the trachea. He inserted the trocar of a Pravaz' syringe into the middle of the trachea, between the first and second cartilaginous rings. A little difficulty was experienced, as the thyroid gland was large, and he only satisfied himself that the point was free by blowing through the canula. The pulse was now 31. No effort at coughing was made, and he thought she had succumbed. Five minutes after, the pulse was 40. The limbs were now covered with warm flannel, and light friction made. In ten minutes the pulse had risen to 45, and an involuntary evacuation occurred. She murmured some words. In thirty-five minutes she asked for some drink. She complained of intense pain in the head, which, however, was not hot. In an hour the pulse had risen to 96; and shortly afterwards she was in her ordinary health.—*London Lancet*.

POISONING BY OPIUM OF A SUCKLING BABE THROUGH ITS MOTHER.—The *Boston Medical and Surgical Journal* says, "In our foreign exchanges we learn of a case of poisoning of an infant by opium administered to the mother. The latter was about to undergo an operation, and at ten o'clock in the morning she took twenty-five drops of Battley's sedative solution, and repeated the dose at two o'clock. At eight o'clock in the evening she took five centigrammes of opium in a pill.

"Her child, a strong boy seven weeks old, was restless throughout the day. At midnight he took the breast, and suddenly fell into a deep sleep, in which he remained for six hours. On awaking he sucked a little, and again slept throughout the day. At two P.M. respiration diminished in frequency, and became less deep and jerking. At six P.M. the pupil was contracted, respiration imperfect, jerking irregular, but in frequency nearly normal. It was with great difficulty that he could be aroused. Coffee was administered by the mouth and by the rectum, and the patient was exposed to the draught from an open window, and in about an hour he seemed better. An hour later, respiration ceased for a while, and he appeared dead; life, however, returned, and the following day, by two A.M., he was out of danger."

ALCOHOLIC SOLUTION OF BROMINE IN UTERINE CANCER.—Henneberg (*Centralblatt für die Med. Wis.*) reports six more cases in which the alcoholic solution of bromine (1.5) was proved to be of undoubted value, both in the after-treatment of the wounded surfaces after the enucleation of the cancer and in its direct application in the form of parenchymatous injections and tampons. Henneberg has further tested the action of bromine on cancerous neoplasms in various extirpated tumors. Portions of the tumor which were placed in the solution and left to remain in it for forty-eight hours, on being removed showed only fibres of connective tissue with isolated (*Spiegel*) mirror-cells. In the case of a freshly extirpated cervical cancer, the cancerous masses were found destroyed throughout.—*Med.-Chir. Centralblatt*, No. 18, 1875; *New York Medical Journal*.

REMOVAL OF BREAST BY ELASTIC LIGATURE.—M. Fériér presented to the Société de Chirurgie a cystosarcoma of the breast which he had removed from a female eighty-four years of age, who was in a very

enfeebled condition. The tumor, existing for twenty-four years, was of the size of the fist, movable, and separated by its weight from the adjacent parts. The operation consisted in passing a band of rubber through the base of the tumor, and afterwards tightening it by clamps. The tumor during the first days assumed a reddish color, then became blue, and finally fell off. The patient, a few months later, succumbed to an attack of erysipelas of the face. The author believes that the elastic ligature in removal of tumors is preferable in old people to every other method, and that in employing it we avoid the loss of blood which is inevitable in the cutting operation; cicatrization is more rapid than after the use of the galvano-cautery; lastly, anæsthesia is dispensed with.—*Revue de Thérap. Méd.-Chir.*; *New York Medical Journal*.

ERYSIPELAS FROM APPLICATION OF ARNICA.—A further case of inflammation of the skin following the application of tincture of arnica is reported in the *Wiener Med. Wochenschrift*. An elderly clergyman, who had been in the habit of applying the tincture for every external injury, having sustained a severe bruise of the left knee, applied the diluted tincture; soon afterwards the skin became hard, red, and swollen, and in five hours this swelling had extended over the entire left lower extremity up to the hip, and was accompanied by much heat and itching; it subsided in about fifteen hours without desquamation. The author, Dr. Koller, states that as the tincture of arnica is used by the peasantry in all injuries, he has very often observed this inflammation of the skin, which closely resembles the erythema after bites from insects, after the use of even the diluted tincture.—*New York Medical Journal*.

TREATMENT OF NEURALGIA IN THE MAMMARY GLAND.—In these cases Prof. Broca has returned to the treatment which was employed by Récamier. Whether the tumor is appreciable or not, as soon as there is pain or sensitiveness he has recourse to methodical compression. Récamier superposed a series of disks of amadou, applied closely, and held in place by a very tight bandage, and this bandage was only renewed at long intervals.—*Revue de Thérap. Méd.-Chir.*; *New York Medical Journal*.

GLEANINGS FROM OUR EXCHANGES.

OVARIOTOMY.—In a paper read before the Suffolk District Medical Society, Dr. James R. Chadwick describes the removal of a unilocular ovarian cyst. The abdominal walls were found to be very thick; an incision four inches long was made in the median line, a Wells clamp was applied to the pedicle, and the wound closed with silk sutures. Two gallons of fluid were in the cyst. The total weight of the tumor was eighteen pounds.

The recovery from ether was speedy and unattended by vomiting. Morphine to the extent of a grain was required to relieve the pain apparently due to the traction on the pedicle. Three hours after the operation the patient was dozing, so that he ventured to leave her in charge of the nurse for half an hour. On his return, however, he found her in a state of profound collapse, almost pulseless, scarcely breathing, blue, and clammy. Brandy and heat had already proved ineffectual to arouse the vital forces. He immediately removed the dressings from the wound, and, finding the abdomen considerably distended, took out nearly all the sutures, broke up the agglutinations, and allowed much serum to escape: on search, no effusion of blood was discovered in the peritoneal cavity. The patient revived at

once. The pedicle seemed so tense that, before reclosing the incision, he tied it firmly below the clamp, removed this, and dropped the pedicle in Douglas's pouch. A similar sudden revival from imminent death was observed in 1867 by Koeberlé, who, during an acute peritonitis subsequent to ovariectomy, made an incision into the right flank, where dulness was detected, and allowed a large accumulation of pinkish serum to escape. The patient rallied at once and made a good recovery. Dr. Chadwick's case did well for the following three days, but on the fourth day the intestines became greatly distended with gas, interfering so much with respiration that it became necessary to puncture them. This gave great relief, but she sank and died on the fifth day. After her death it was discovered that her habits had been very intemperate, although she had, previous to the operation, positively denied that this was the case. Dr. Chadwick unhesitatingly attributes the fatal result to exhaustion depending upon the condition induced by the immoderate use of alcoholic stimulants.

In connection with the puncturing of the intestines with the aspirator to relieve the flatulence, it seems as if another indication may be met by injecting brandy, beef-tea, etc., through the canula into the small or large intestine, after the gas has escaped. By this means a patient's strength might be sustained when nothing could be retained in the stomach and absorption by the rectum was too slow to meet the demands of the system. In this way fluids could be introduced in considerable quantities into that part of the alimentary canal from which they would be most readily absorbed. If the use of the trocar is as harmless as is asserted by those who have tried it, there is no reason why the intestines should not be repeatedly tapped for the injection of nutrient and stimulant fluids in many desperate conditions and diseases, when the other resources of medical art have failed. In such a case as this, there would have been no other means of introducing enough alcohol to carry her through the depressing effect of such an operation, had her habits been made known during life. Might not peristaltic action also have been excited by the same measure, and thus a second advantage been derived from this procedure? In cases of fecal impaction, may not the hard, scybalous masses be softened and broken up by the injection of different fluids into their midst, when enemata and purges have proved powerless?

AUTUMNAL CATARRH (*Boston Medical and Surgical Journal*, August 19, 1875).—Dr. Morrill Wyman alludes to the approach of the season when autumnal catarrh, or "hay-fever," as it is popularly called, although there is no evidence that it has anything to do with hay as a cause, sets in and runs its course. He advises those who are able to change their residence to leave, if possible, before the annual return of the disease, and to seek elevated localities. To those who cannot get away he gives the following directions. Avoid the direct rays of the sun, the dust of the street, and the smoke of railway-trains; avoid also such plants as Roman wormwood, golden rod, and others, which are known to bring on an attack. The sleeping-room should have an open fireplace, should not be exposed to the afternoon sun, and, after being well aired for an hour in the early morning, should have the doors and windows closed and kept closed until the following morning. The diet should be nourishing, containing animal food. Alcoholic stimulants should be avoided. Flannels should be worn from the middle of August and increased in warmth as the season and disease advance.

Of medicine, quinine has been of the most use as a preventive and a relief to the most annoying symptoms. Its use should be commenced a week or ten days before

the usual return of the disease, and continued through its course, in doses of one to two grains with each meal. Gentle saline or other laxatives are useful, but violent purging should be avoided. For itching of the eyes, mouth, and throat, a saturated watery solution of quinine, made without the addition of any acid, may be used locally with an atomizer.

The irritation and discharge from the nostrils may be relieved by the "head-bath," holding the head for five minutes over a bowl of very hot milk-and-water or water alone, the head and shoulders meanwhile covered with a shawl. In railway-travelling and on dusty roads much relief is gained by placing small pieces of wet sponge just within the nostrils, or covering the whole face with Swiss muslin wet with water. The nostrils are often completely obstructed early in the morning, and swallowing impeded: this may be relieved temporarily by active movements of the limbs for a few minutes,—leaping or running quickly up-stairs,—after which one can often eat his breakfast with comparative comfort.

For the night, a closed room, and, if opium can be taken without inconvenience, six or eight grains of Dover's powder or an equivalent in laudanum or a solution of morphine, often give more or less freedom from that most annoying symptom in the later stages, the spasmodic cough. It may also be relieved by the spray from the watery solution of quinine as just mentioned. The common household mucilaginous remedies, gum arabic and flaxseed tea, for temporary relief are not to be rejected. The asthma, like that occurring at other seasons and produced by other causes, is often spasmodic, nervous, and wayward; it is relieved by a variety of remedies: the inhaling of the smoke from burning stramonium leaves and saltpetre, three parts of the former to one of the latter, probably gives as much relief to a majority of sufferers as any other treatment.

BILATERAL SECTION OF THE CERVIX UTERI (*The Clinic*, August 7, 1875).—Dr. J. C. McMechan refers to the employment of the operation of bilateral section in cases of uterine flexion, in constrictions of the cervical canal or the external or internal os, in sterility, in hyperplasia or severe neuralgia of the cervix. He describes his method of operating as follows: "The left arm must be drawn behind the patient so as to let her rest on the left side of the chest, and the right leg be so flexed as to let the right knee lie just above the left. This is the position recommended by Sims. The patient can now be chloroformed or not, as desired; but this is often not necessary, as the operation is not painful, and lasts but a few minutes. The speculum is now introduced and held by an assistant whilst the operator inserts the tenaculum into the substance of the cervix, and by gentle traction draws the cervix down to the pudenda; one blade of the scissors is to be inserted into the canalis cervicis and the other passed up to the insertion of the vaginal arch, and the incision is then to be made. The other side is to be treated in the same manner. If it be necessary to relieve a constriction at the internal os, it may be done by means of a narrow, blunt-pointed knife; but, according to Barnes, this is but seldom necessary. If much hemorrhage takes place, the cut surface is to be plugged with lint saturated with a solution of persulphate of iron. In the *Wiener Medizinische Wochenschrift* for 1869, Prof. Gustav Braun reports sixty-seven cases of bilateral incision. Fifty-three of his cases resulted favorably."

CHRONIC ENLARGEMENT OF THE TONSILS IN RELATION TO DEAFNESS AND CERTAIN SPASMODIC PHENOMENA (*The Western Lancet*, July, 1875).—Dr. F. W. Godon reports a number of cases of enlarged tonsils in all of which there were frequent attacks of subacute inflammation, accompanied by dysphagia, dryness of

the throat, and hoarseness of voice. In all the adult cases there existed a variable amount of inflammation or congestion. Deafness was in each case a prominent and an alarming symptom, and some of the patients were markedly affected by it, while some presented unusual spasmodic phenomena.

The result of excision of the tonsil was uniformly favorable.

The majority of cases of this kind are regarded as asthma, or as cases of deafness resulting from cold or nervous shock, but little stress being laid upon former throat-troubles. Many cases of so-called deafness from cold depend on a chronic hypertrophy of the tonsils, producing great thickening of and resulting in closure of the pharyngeal orifice of the Eustachian tube, by pressing the palate against it. The affection cannot be recognized by a mere glance at the throat, for sometimes the entire circumference cannot be seen by inspection alone, and in such cases the finger should be made use of in the examination and the gland will be found to be enlarged above and below. Usually the patient complains of sore throat at the time of consultation, and gives in addition a history of successive attacks of sore throat; but, inasmuch as the affection may be chronic from the start, no history of throat-trouble may be given at all. The treatment should be, in all cases of this kind, excision of the tonsils, with proper local applications, when all the painful symptoms will quickly and permanently subside.

FOREST CULTURE AS A PROPHYLACTIC TO MIASMATIC DISEASES (*Pacific Medical and Surgical Journal*, August, 1875).—Dr. W. P. Gibbons, in an able paper on the above subject, comes to the following conclusions. That forest trees in sufficient numbers will absorb, from deep as well as from superficial strata, a sufficient quantity of water to establish regular subterranean currents, and that whatever miasm may be combined with or held in solution by the water will thus be carried off, or have its toxic properties in whole or in part neutralized; that the water thus exhaled will be diffused through the atmosphere in such quantity as to be returned in great part to the surface-soil by precipitation; that the high summer temperature may thus be so modified as to reduce the nocturnal heat below 60°; that the causes thus operating to prevent vegetable fermentation, or to dissipate miasm if developed, would protect the valley from regular visitations of paludal fevers; that the modification of climate thus induced would, under ordinary circumstances, insure average crops of grain in localities which are now dependent either on unusually wet seasons or on artificial irrigation; and that, while immediate benefits would thus be conferred upon the farmer by extensive tree-planting, the remuneration would be cumulative, not only in the regularly increasing value of his timber, but in the prospective reclamation, by natural process, without absolute expense, of land which is now utterly useless.

THE HYPODERMIC USE OF APOMORPHIA AS AN EMETIC IN CHILDREN (*Medical Record*, August 7, 1875).—Dr. William F. Duncan, after considerable experience with apomorphia, says that the qualities which recommend it particularly are the rapidity of its action, the absence of danger from an over-dose, the lightness of its secondary effects, the shortness of the period of nausea, the easy manner of its introduction.

The average time at which emesis has occurred, after the introduction of this drug under the skin, is 2.9 minutes, which is very much less than the shortest time noticed when using the yellow sulphate of mercury.

The longest time for emesis to appear was 4.15 minutes, in a case of alcoholism, while the shortest was 1.75 minutes, in a case of capillary bronchitis.

The dose of apomorphia, hypodermically used, for an

adult, ranges from gr. $\frac{1}{10}$ to gr. $\frac{1}{20}$, but in children it is quite large in proportion.

For a child of 18 months	gr. $\frac{1}{50}$.
" " 2 years	gr. $\frac{1}{40}$.
" " 3 "	gr. $\frac{1}{35}$.
" " 5 "	gr. $\frac{1}{30}$.
" " 8 "	gr. $\frac{1}{25}$.

Glycerin seems to preserve the strength of the drug, and alcohol will dissolve it more readily than water: so that it should be prepared after the following formula:

R Apomorphiæ, gr. vii;
Spt. rectificat., ℥xx;
Glycerin., ℥x;
Aqua, ℥l.—M.

PROPERTIES OF GRINDELIA ROBUSTA (*Pacific Medical and Surgical Journal*, August, 1875).—Dr. Henry M. Fiske has employed the grindelia robusta, an herbaceous perennial plant, a native of the west coast of America, in a variety of cases with excellent results. It is a demulcent as well as stimulant, and makes an excellent dressing for vesicated surfaces. In burns, the fresh herb bruised and applied frequently over the injured parts is an unequalled anæsthetic. It is an excellent remedy in uterine catarrh, or in catarrh of the genito-urinary tract. In subduing the intense burning and itching of vaginitis, as well as painful priapism, it is of great value. In the first, the tincture or fluid extract, of the strength of one tablespoonful of either to about four tablespoonfuls of water, should be used as an injection three or four times a day, and cloths should be soaked in it and applied to the pubes as hot as can be borne. In the other, a direct application should be made of the bruised plant, in the form of a poultice, if possible, changed frequently. In a few hours marked beneficial results will be noticed. In iritis, no matter what the cause, whether gout, rheumatism, scrofula, or violence, it seems to be almost a specific. Dr. Fisk gives two cases of iritis in which he employed grindelia with excellent effect.

THE EMPLOYMENT OF CHLORAL AS AN ANÆSTHETIC IN NATURAL LABOR (*The Obstetrical Journal*, August, 1875).—Dr. H. Choupe concludes from a number of observations that chloral is a powerful anæsthetic, capable, when it is given in a sufficient dose, of suppressing completely the pains provoked by the uterine contractions. The suppression of the pain, so advantageous in numberless instances, is not obtained at the expense of the regularity and rapidity of labor. The uterine contractions lose nothing, either in frequency or in force, by its administration. If in any case they seem to recur less often than before the administration of the drug, what they lose in frequency they gain in force. In suppressing the pain and the excitation which it provokes, chloral generally hastens the termination of labor, and may be employed without any inconvenience to the mother or the infant. It is especially among excitable women, who have wasted their powers in the first part of labor, and among hysterical patients, that chloral is indicated. Whatever it may be, when it is decided to employ chloral it is necessary to give it in a sufficient dose to produce useful effects, and not to lose by too much circumspection the advantages of a valuable remedy.

POISONING BY PICKLES (*Boston Medical and Surgical Journal*, August 19, 1875).—Dr. H. Lossing reports a case of a family who, after eating pickles, were affected with symptoms of irritant poisoning which were only allayed by active and continued treatment. The "vinegar" in which the pickles were contained was found to be a dilution of impure sulphuric acid, in which were also iron, arsenic, and oxalic acid. Large quantities of this stuff are sold all over the country.

MISCELLANY.

THE LOCALIZATION OF SENSORY CENTRES IN THE BRAIN.—At a recent meeting of the British Medical Association, Dr. Brunton read a paper communicated by Dr. Ferrier, containing an "Abstract of Experiments on the Brains of Monkeys, with special reference to the Localization of Sensory Centres in the Convolutions." The experiments, which were conducted by trephining and the destruction of the sensory centres by means of a red-hot wire, led to the following results. These centres are bilateral, so that when one of the centres of touch was destroyed, there was loss of tactile sensibility in the corresponding half of the body. Stimulation of the centre of hearing caused the animal to prick up its ears as if it heard something, while destruction of the whole of this centre rendered the creature totally deaf. Destruction of the centre of vision corresponding to one eye (*e. g.*, the right) only rendered the animal temporarily blind in that eye, the function, after twenty-four hours, being carried on by the opposite centre. In the discussion that followed, Dr. Nairne pointed out that other observers had arrived at conclusions different from those of Dr. Ferrier, and that the brain of the monkey could not be taken as exactly similar to that of a man; but Dr. Brunton thought the mistake made by German and other investigators who differed from Dr. Ferrier was, that they took the brains of animals lower even than the monkey to correspond with that of man. M. Dupuy had arrived at different results. He said that he had found that when the centres of motion on one side of the brain were removed, paralysis followed for a short time throughout the corresponding part of the body, but that when the centres were removed from both sides of the brain there was no paralysis at all.

PARIS AND LONDON IN 1874.—The *Bulletin récapitulatif de Statistique municipale*, relating to Paris for 1874, has just been issued by the Préfet de la Seine. It corresponds with the Registrar-General's Annual Summary for London, and although its statistics are published in a far more elaborate form than those for London, they afford the means for a comparison between the vital statistics of the two largest cities of the world. The population of London in 1874 was very nearly double that of Paris; the density of population in persons to an acre was, however, only 44 per acre in London, whereas it was 96 in Paris. The marriage-rate was 8 per 1000 in London, and 10 in Paris; the birth-rate 35 in London, and 29 in Paris; and the death-rate 21.6 in London, and 22 in Paris. Whereas the marriage-rate in Paris exceeded that in London by 25 per cent., the birth-rate in Paris was 20 per cent. below that in London. The death-rate in the two cities in 1874 showed little difference, and yet, in consequence of the variation between the birth-rates, the natural increase in the population during the year, by excess of births over deaths, was equal to nearly 14 per 1000 in London, whereas it was not more than 7 per 1000 in Paris. Notwithstanding that the marriage-rate in Paris considerably exceeds

that in London, the proportion of illegitimate births in Paris was nearly 27 per cent., while in London it is only about 4 per cent. With regard to the mortality statistics, the annual Paris Bulletin contains information in far greater detail than the London Annual Summary. The rate of mortality is given for each of the twenty arrondissements and for each of the eighty quarters into which Paris is divided. In the twenty arrondissements the death-rate in 1874 ranged from 15 per 1000 to 27. It is somewhat remarkable that in the arrondissement in which the density of population is greatest in Paris—namely, more than 300 persons per acre—the death-rate did not in 1874 exceed 16 per 1000. London figures show a very different result.—*London Lancet*.

CULTIVATION OF NUTMEGS IN JAMAICA.—According to Mr. R. Thompson, Colonial Botanist, Jamaica (*Journal of Applied Science*), the cultivation of the nutmeg-tree is very successfully carried on on that island. A number of plants have been supplied, and about two thousand are now under propagation at the Bath Gardens, and will shortly be ready for distribution. A fine nutmeg-tree growing in the vicinity has a crop of about four thousand unusually large fruits. At present prices, this quantity—calculating ninety nuts to the pound—will realize about twenty-two dollars. However, this crop appears to be considerably above the average, as five dollars is the usual value of the annual produce of one tree. The nutmeg begins to bear about the seventh year, and the price of the fruit depends largely on the size, or number to the pound. Large nutmegs count about eighty to the pound.—*Canada Pharm. Journal*.

A HEAVY DOSE OF MERCURY.—"A few days ago," says the Gilroy (Cal.) *Advocate*, "Mrs. Anna Babb's little boy drank a pound of quicksilver. The child is less than three years old, and even in California is considered rather young to indulge in so strong a beverage. He found the mercury-bottle in some rubbish in an old trunk, while playing, and drank the whole, leaving but a few drops. The physician was sent for, who administered some light remedy. The child gave no other indication of having taken the mercury than drowsiness. The metal did not all leave the stomach for ten days, but he was about all the time, and is now as bright as ever."

A TRAINING-SCHOOL FOR NURSES.—The plan of management of the training-school recently established at Montreal, as given by the *Canada Medical Journal*, is as follows: Each nurse binds herself to serve three years, the first six months free, and after that to receive ten dollars per month and two suits of uniform annually, and comfortable board and lodgings at the "Home" when unemployed. The expenses have been met by private subscription, and the concern is now nearly self-supporting. It contains about forty beds.

LOCAL ANÆSTHESIA IN CASES OF LABOR.—Dr. Friedlander relates that, being called to a woman who was suffering intolerable pain in the sacral region, he re-

sorted to an application of chloroform (one part) and ether (two parts), after having vainly tried several other means. He obtained by this means total cessation of all pain until perfect delivery. After having successfully tried the same application in a great many cases, he recommends its employment as an anodyne for the pains of parturition.—*Deutsche Klinik; Lancet*.

EXTRA FEES.—With a view to encourage patients and others who may be in need of the attendance of a physician to send him word at such time as will admit of his arranging his work for the day, the Forfarshire (Scot.) Medical Association have confirmed the resolution unanimously adopted at last year's meeting, "that all visits sent for at 10 A.M., and requiring to be attended to the same day, should be charged at an extra rate."—*Ex*.

AN OLD SAYING.—A contemporary says that "leucocythæmic histomorphoses antitype septicæmic prodromata." This is what every physician has repeated daily to his friends and family; indeed, physicians never converse socially with each other without using as a preface this admirable and appropriate salutation.—*American Weekly*.

DR. J. W. BECHTEL, of Harrisburg, was convicted, August 31, of attempted malpractice on Amanda Earnest, of Hummelstown. Her betrayer, Henry G. Walmer, was found guilty as an accessory.

THE SEXTON'S POEM.—

"It was a cough
That took him off;
It was a coffin
They took him off in."

THE session of the London medical schools commences October 18.

NOTES AND QUERIES.

COMMUNICATIONS have been received from "Peter Aarundel" and "Knowledge-Seeker." These authorities are hereby respectfully informed of the long-existing rule that communications, in order to be published, must be accompanied by the name of the writer, even if the latter is to remain unknown to the general public.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM AUGUST 31, 1875, TO SEPTEMBER 6, 1875, INCLUSIVE.

WEBSTER, WARREN, SURGEON.—Granted leave of absence for one month. S. O. 174, A. G. O., August 30, 1875.

MIDDLETON, J. V. D., ASSISTANT-SURGEON.—Leave of absence further extended one month. S. O. 49, Headquarters of the Army, August 30, 1875.

HUNTINGTON, D. L., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Price, to comply with par. 5, S. O. 158, c. s., A. G. O. S. O. 93, Department of California, August 25, 1875.

O'REILLY, R. M., ASSISTANT-SURGEON.—Relieved from temporary duty at Fort Hamilton, New York Harbor, and to rejoin his station, Fort Hamilton, New York Harbor. S. O. 175, Military Division of the Atlantic, September 3, 1875.

AINSWORTH, F. C., ASSISTANT-SURGEON.—Assigned to duty at Fort Vancouver, Washington Territory. S. O. 115, Department of the Columbia, August 19, 1875.

PRICE, C. E., ASSISTANT-SURGEON.—Assigned to duty at Angel Island, California. S. O. 93, c. s., Department of California.

SATURDAY, SEPTEMBER 18, 1875.

ORIGINAL COMMUNICATIONS.

ENUCLEATION OF TWO VAGINAL FIBROIDS, CONTAINING LYMPHATICS—LYMPHANGIOMA FIBROSUM.

BY JAMES R. CHADWICK, M.D.,
of Boston.

Read before the Obstetrical Society of Boston.

MISS L., 32 years old, began about six years ago to have epileptiform attacks during menstruation. They were not constant in their attendance upon the menses, but occasionally skipped a month. During the past year they have sometimes recurred during the intermenstrual periods, but, on the whole, have not increased in frequency. The spasms are invariably preceded by aura, which is described as a faintness first felt in the left ovarian region, passing thence to the heart and on to the head, whereupon loss of consciousness immediately ensues. The patient has arrested many attacks by pressure in the ovarian region. The convulsions last about fifteen minutes, during which time the patient turns black in the face, has general tonic spasms, her jaws are rigid, she foams at the mouth, and often bites her tongue. On one occasion she broke a tooth against a silver spoon. From this she passes into a stage of delirium, during which she screams, talks wildly, etc. This subsides after a few minutes, and leaves her free from any ill effects, and perfectly able to resume her daily task.

These were all the data that I obtained at my first visit, several months since. Of course the question at once arose, Was this disease epilepsy, or was it only the functional nervous affection called hystero-epilepsy? The distinctive traits were recently portrayed by Charcot* in a clinical lecture as follows: "In hystero-epilepsy the premonitory symptoms are apt to be of rather long duration, and consist principally of an aura, which, starting in most cases from the ovarian region, advances progressively to the head. The cry is prolonged and modulated, not short like the epileptic. The convulsions are identical in the two affections. Instead of entering subsequently upon a stage of snoring, the hystero-epileptic is delirious and subject to hallucinations; there is, however, no maniacal excitement or violence. In the ovarian form of hystero-epilepsy, pressure upon the ovary will invariably modify the symptoms, if not completely arrest the attack; in epilepsy no effect is produced. With the lapse of time the hystero-epileptic becomes capricious, fantastic, but very rarely irascible, gloomy, or dangerous."

My patient presented enough of the symptoms peculiar to hystero-epilepsy to prompt a more particular inquiry into the condition of her sexual functions. She reluctantly confessed to the presence of a tumor at the vulva, first observed at about the

time when the convulsions began to manifest themselves. It had not increased much in size or given rise to discomfort, except at her menstrual epochs, when it had always swelled to double its volume, often causing retention of urine as well as of the menstrual flow. Her sufferings from these causes were often intense.

Examination revealed an oval, elastic tumor, as large as a walnut, lying precisely beneath the arch of the pubis, between the anterior vaginal wall and the urethra, and projecting into the vaginal canal, so as nearly to occlude the opening in the hymen. The uterus was quite independent. On learning that this was probably the exciting cause of her convulsive attacks, the patient readily consented to its removal; but a month elapsed before I saw her again. She then reported that at the last catamenial period the tumor had swelled to unwonted dimensions, had protruded from the vulva, whereupon she had picked off two dry scales from its surface. The tumor had since remained large, protruding, and at the two spots mentioned the tissues had budded out; she had, moreover, had three very severe spasmodic attacks within the month, instead of one in two months, as heretofore. I found that, owing to the constriction of the hymen, the growth or swelling had been forced down until it appeared pedunculated; on its anterior surface there were two mushroom-like excrescences covered with exuberant granulations; these are still visible on the larger specimen; there appeared to be an attempt at spontaneous enucleation.

At the operation on the next day it was only necessary to cut the narrow strip of vaginal wall and capsule intervening between these two excrescences, when the tumor, nearly as large as a hen's egg, was readily enucleated with the handle of the scalpel. This second tumor, the size of a bean, was found in a distinct capsule, near the first, and removed. Ligatures were applied to a few bleeding points, and the lateral edges of the incision brought together with silk sutures. There was no union by first intention, but after three weeks the opening had completely healed.

In their gross appearances these tumors would be grouped with fibroids of the vagina, of which I find only a few on record.

Kiwisch† cites two cases, reported by Gremler and Pelletan respectively. The former writer removed a ten-pound fibroid tumor, which hung by a pedicle from the introitus vaginæ. The latter enucleated a similar growth from its site to the right of the vagina, where it extended from the rectum to the bladder, interfering with defecation and micturition.

Paget,‡ after referring to the cases of Brodie, Hawkins, Curling, and O'Ferrald, describes a tumor which originally projected into the vagina from beneath its right wall. One or two punctures caused it to take on a more rapid growth, whereupon it was dissected out without difficulty. Traetzl§

* Abstract in London Medical Record, March 18, 1874.

† Klinische Vorträge, ii. 558.

‡ Lectures on Surgical Pathology, vol. ii. p. 116.

§ Monatsschrift für Geburtskunde, xxii. 3, 227.

removed a fibroid as large as a man's fist, which was protruding from the vagina of a child fifteen months old. The seat of its attachment is not given.

McClintock* has met with three instances of this growth. His description of the first corresponds almost precisely with my own case. The growth was, however, removed by ligature, giving rise to a sloughing of the mass with hemorrhage and prostration, but resulting ultimately in recovery.

In the second and third cases the tumors depended by pedicles from the post-vaginal wall. They were taken off with the *écraseur*.

Hecker,† in 1855, excised a fibroid tumor, as large as a walnut, from just behind the left nymphæ.

West‡ speaks of a case then under treatment, as probably being a fibroid tumor. It was three fingers long, lay in the direction of the urethra, "pushed the uterus into the hollow of the sacrum, but was quite independent of this organ."

Meadows§ met with a tumor about the size of a turkey's egg, which projected from the vulva, and was adherent to the vagina on all sides; it was for a while supposed to be a prolapsed uterus. The adhesions were, however, separated, and the growth traced up between the bladder and the uterus. As much as possible of the mass was removed with the *écraseur*; but the patient died on the seventh day with symptoms of embolism. The uterus proved to be independent of the tumor, which appeared to have sprung from the fibrous tissue of the anterior vaginal wall.

A few more cases might be adduced, but I have quoted authorities enough to show that the origin of fibroid tumors in and about the vaginal walls, quite independently of the uterus, is firmly established. The most common site seems to be between the anterior vaginal wall and the urethra.

In only one instance, that of Hecker, was any microscopic examination of the tumor mentioned in the reports; his tumor was found to be "purely fibroid structure."

My tumors proved unexpectedly to be of peculiar, I may say almost unique, microscopic character, as may be seen from this description of the specimen by Dr. R. H. Fitz:

"Sections removed from the tumor were, after being stained with hæmatoxylin, mounted in glycerin and Canada balsam. The tissue was found to be exceedingly rich in delicate vessels, not containing blood, anastomosing with one another in a very intimate manner; the intervening spaces were more or less circular, and contained a fibrillated substance in which were occasional round and innumerable stellate cells. The latter were, in many instances, directly continuous with the vessels previously mentioned, particularly with the smaller ones, which were likewise stellate in their distribution, and apparently differed from the stellate corpuscles only in being more voluminous and having more abundantly nucleated walls. On the addition of acetic

acid, the intercellular substance became homogeneous and translucent. Although the tumors possess the general characteristics of fibromata, they are peculiar in containing such numbers of anastomosing tubes of the nature of lymph-vessels. The term lymphangioma fibrosum would most nearly indicate the apparent character."

It seems to me probable that a microscopic examination of some of the other vaginal fibroids would have disclosed similar histological elements. It is highly desirable that such tumors should be more carefully studied in the future.

I regret to say, in conclusion, that there has been no abatement in the frequency or violence of the epileptoid attacks, despite the successive administration of the bromides, iron, quinine, free phosphorus, etc., etc. The uterus is not enlarged or displaced, but its mobility is more restricted than usual; to its left there is an ill-defined resistance, upon touching which the same sensations are excited as constitute the epileptoid aura. There is no history of peritoneal or cellular inflammation, and no reason for thinking that the resistance is due to any kind of effusion. The practical question arises, Would the removal of the left ovary or the offending body cure the convulsive affection?

CHLOROFORM IN MALARIA.

BY JOS. BERENS, M.D.

THERE is nothing new or original in the treatment of malaria by the internal use of chloroform.|| The absolute desuetude, however, into which the remedy has fallen, coupled with the incontrovertible fact that the potency of quinine is not invariably sustained, the difficulty, also, of obtaining the latter under certain circumstances of poverty or accident, have suggested the publication of the following cases. They occurred in the wards of the Philadelphia Hospital, under the charge of Dr. H. C. Wood:

Case I.—M. B., æt. 37, eight years ago, while living in a malarial district of the city, contracted fever and ague, which disappeared permanently at the end of nine months. There was no recurrence until three weeks previous to admission, she had a second attack while living in Pemberton, New Jersey. The chills are of the pure tertiary type, appearing regularly at three o'clock every second day, and for which she has been under no treatment. She has had two most unequivocal paroxysms since admission, and expects another this afternoon. Ordered half a drachm of chloroform hourly for three hours preceding the attack; a full drachm at the time of attack. Patient had an hour's sleep after last dose, but no chill nor any subsequent febrile excitement. This was on the 23d of November. The same treatment was applied on the following chill days until December 2, after which no more chloroform was administered. During this time there was no renewal of the paroxysms, while the condition of the patient steadily improved. The patient has been under observation at intervals up to the present, and as yet has had no symptom of a return of her trouble.

Case II.—Mary C., æt. 40, entered the house October

|| Vide Flint's Practice of Medicine, p. 928.

23, suffering from a quartan ague of two weeks' standing and of moderate severity. The day following her admission, at 10 A.M., she had a well-defined chill and subsequent fever.

Oct. 24.—Ordered a drachm of chloroform every hour for three hours before the expected seizure. Patient slept almost continually from the first dose until an hour after the last. She missed her usual attack altogether.

Oct. 25.—Through the carelessness of the nurse, the patient did not get her medicine. At the usual time there were a few crawling sensations, or rather a feeling as though she were going to have a chill; this was of a half-hour's duration, and followed by considerable fever.

Oct. 26.—To-day she received her medicine as directed, and slept over the time for her attack, without an unpleasant symptom.

Oct. 29.—Patient has been very ill all day, from the combined effects of a chill and aggravated hemorrhoids. The chloroform seemed to have little or no effect, excepting to make her very drowsy.

Oct. 30.—Chloroform as usual, with the effect of preventing the chill.

Oct. 31.—Four hours before the expected attack, she had a severe shake, succeeded by high fever. Chloroform administered in twenty-drop doses every hour, with the effect, as the patient stated, of alleviating the attack.

November 1.—Began the administration of the remedy four hours earlier. She escaped her chill.

Nov. 2.—At 4 A.M., just before taking the first dose of medicine, she had a moderately pronounced chill, after which there was intense fever, with great prostration. Chloroform administered as before, but with no appreciable effect.

The next time treatment was begun at midnight, and the day following at 10 A.M., with the effect of preventing an attack. From this until the 7th there was no attack, although no chloroform was administered.

On the 7th there was a chill at 6 A.M.

Nov. 13.—The paroxysms have been carefully anticipated, with the result of preventing their repetition. Treatment discontinued.

December 15.—There has been no return of the malarial trouble. Patient discharged.

Case III.—C. D., æt. 35, entered November 5; states that he has had fever and ague for two weeks. Has a chill every day at 9 A.M.

Nov. 7.—Yesterday had a decided malarial paroxysm at the stated time. This morning the attack was anticipated for three hours by hourly doses of a drachm of chloroform, with the desired effect.

Nov. 10.—Treatment has been continued with entire success. Treatment discontinued.

Nov. 23.—Discharged at his own request, having had not a symptom of malaria after the first dose of chloroform.

Case IV.—H. McP., æt. 22, entered the house on October 22, suffering from quotidian ague of an unusually severe type. She had a similar attack about a year previous, but for the past few months has had no trouble until three weeks ago, when, she says, her chills returned more violently than ever.

She has been under treatment outside, and appears to have been thoroughly dosed with quinine. She expects her chill in five hours; ordered five grains of cinchona every hour till then. The chill appeared with unabated vigor. During the sweating stage she took fifteen grains more of the cinchona, and in the course of a few hours was well influenced by the drug. The day following she received five-grain doses hourly for four hours before the attack. At the appointed time the chill appeared, the extreme violence of the attack not seemingly affected by the cinchona. The day following, quinine was substituted for cinchona, and Fow-

ler's solution added; this treatment was continued for a week, with no effect in diminishing the force of the attacks. The treatment discontinued, and chloroform ordered in half-drachm doses hourly for four hours preceding the attack, with a full drachm at the time it was expected. *She missed her chill* for the first time, and felt much better than usual. The chloroform retained its power to control the paroxysms for eight days, when it was omitted. At the proper time the day following, the patient complained of feeling cold, but had no perceptible chill; the chilly sensation was followed by a moderate fever, which lasted some hours. The next day the chloroform was resumed. The chill was prevented; there was a little feverishness; pulse 92, temperature 100½°.

For six days the treatment was continued with excellent results; on the seventh and eighth, however, there was a return of the chills in spite of the regular administration of the remedy. Quinine and arsenic were now resumed. The day following there was no chill. This effect lasted for three days, when the symptoms returned with full force. Chloroform was now added to the quinine and arsenic. The effect was most happy for five days, when there was a slight chill, after which the temperature ran up to 105°. The same treatment was now persisted in during the following two weeks; during the time she had one severe chill and two insignificant ones. At the end of this time she passed into other hands, and received no more chloroform, although the quinine and arsenic were continued *ad libitum*. The malady re-asserted itself with great virulence, and continued till the patient died of an intermittent pneumonia some months later.

Even recollecting that a certain proportion of cases of malaria tend to a spontaneous recovery, there are reasonable grounds for attributing the benign course of the disease, in the majority of the cases quoted, to the remedy employed. The patients themselves seemed to entertain little doubt on the subject, and chloroform soon gained a reputation in the wards. In Case IV., particularly, the results were most pronounced: here bark and arsenic seemed to possess little power to control paroxysms which yielded, in part at least, to chloroform.

It may be incidentally remarked, before closing, that ether was used in four cases with the view of comparing its effects in this direction with those of chloroform; its value would seem to be incomparably inferior, for, though it undoubtedly exercised some controlling influence, in no instance did the disease subside during its exclusive employment.

NON-MALARIOUS ORIGIN OF INTERMITTENT FEVER.

BY THOMAS H. STREETS,

Assistant-Surgeon U.S.N.

INTERMITTENT fever occurred several times on board the United States steamer "Portsmouth" during her recent extended cruise, and it was always accompanied by such conditions that I was forced to believe that it was produced by agencies other than those of a malarious origin.

Still, however, supposing that chills and fevers are produced by miasmata,—a hypothetical substance supposed to be generated by the decay of vegetable matter,—I insist that there are other agents capable

of producing, and which do actually produce, the identical disease; and these latter I hold to be atmospheric changes, thermometric and barometric, inasmuch as, in the instances which I am about to narrate, these changes always either preceded or accompanied the attacks, whose origin cannot be explained rationally on any other grounds.

The ship left New York in midwinter, when the ground was frozen and covered with snow. We passed from the depth of winter to the tropics, and from the tropics to the temperate regions; and when in the vicinity of latitude 40° S., in the South Atlantic, we encountered a damp, chilly belt, where fogs prevail, a region similar to that in the vicinity of the Banks of Newfoundland in the Northern hemisphere. Here the first cases of intermittent fever showed themselves aboard.

On the day before entering this belt, the thermometer registered 75° Fahr. at noon, and the weather was clear and pleasant; on the day following, the thermometer fell to 60° at mid-day, and the weather was damp, chilly, and foggy. On the third day the thermometer fell as low as 55° at mid-day. During these three days we passed through about three degrees of latitude, for the winds were light and variable.

Another notable instance, when the same thermometrical changes were experienced, and which were accompanied, as in the former instance, by the appearance of some new cases of intermittent fever aboard, was when the ship was cruising to the eastward of the Sandwich Islands, in about the region of longitude 135° W. Here the cold polar current that sweeps down along the western coast of North America meets the warm airs of the tropics and causes a condensation of their moisture. The sky is constantly clouded; the weather is damp, foggy, and chilly; and the thermometer ranges from 66° to 69° Fahr. at mid-day. Along with the intermittent fever there appeared in this instance cases of rheumatism, bronchitis, tonsillitis, and neuralgia, all of which I deemed were due to the operation of the same cause.

According to a good authority,—Parkes,—the horizontal spread of malaria is not more than two or three miles. This is overland. A spread of water seems to be more efficacious in checking its progress. Yet, even if it be transferable “ten, twenty, or even one hundred miles,” as is stated by some authorities, our track put us without the limit of its influence in the extreme case: we were over one thousand miles from the nearest land, and taking it in the direction of the prevailing winds, from which the noxious germs would be most likely to come, it was very much farther removed. The only way remaining that I can see to explain the origin of these cases of ague according to the old notion is to say that the germs of the disease were latent in the body, and in this extraordinary state of the atmosphere found conditions favorable for their growth and development; yet this could hardly be applied to those cases that originated *de novo*, of which there were several.

In opposition to the theory of the latency of the germs of the disease, and to the opinion held by

some, that one attack of the disease predisposes to another when exposed to the deleterious agent, I will mention my own experience in Southern Mexico in 1870. I was one of two in a large party who escaped entirely from the malignant fever of that country during a residence there of about eight months. I attribute my immunity to the extreme precaution which I took to keep my body always warm, and not to expose myself to the rains and dews of the night. Slighter changes than could be appreciated here would there cause a decided lowering of the tone of the body in the already enervated state of the system which a residence in a tropical climate generates. I considered myself at the time particularly liable to the disease, for I had, less than a year before, gotten rid of an attack which I had contracted in the bottom-lands of Texas, and which had remained by me for fifteen months. Quinine was given to some of the members of the party, yet it failed to exert any prophylactic properties when not joined with due care to preserve the warmth of the body and to guard against exposure.

Any one who has lived in a malarious tropical country for any length of time, and has been observing, knows full well that the surest way to keep himself free from fevers is to wear flannel next the skin, and to have a roof over his head at night and when it rains. “It has been supposed that wearing flannel next the skin lessens the risk of malaria. As it is generally supposed that the poison of malaria enters by the lungs or stomach, it is difficult to see how protection to the skin can prevent its action, except indirectly by preventing chill in persons who have already suffered from ague. But the very great authority of Andrew Combe, drawn from experience at Rome, is in favor of its having some influence, and it has been used on the west coast of Africa for this purpose with, apparently, good results” (Parkes). I have always found a change to heavier clothing to be a valuable auxiliary in the cure of the disease.

It is hardly probable that the habitations in tropical countries, that have such free ventilation, keep out the invisible malaria, which is freely suspended in the air, penetrating everywhere. What is it, then, that the roofs keep off but the dews and rains?

The native Hawaiian cultivates a root called *taro* (*Arum esculentum*). To cultivate this root successfully it is necessary that the ground should be in a condition similar to that which favors the growth of our Indian turnip. They throw up embankments around patches of land, and then flood it with water until the soil is converted into mud eighteen inches to two feet deep. The root grows in the mud, and the ground is kept so for six months or more in the year. Here are all the conditions requisite for rapid vegetable decomposition; and, as most of the patches are to the windward of Honolulu, the trade-winds are constantly sweeping the malaria over the town; yet intermittent fever is a very rare disease there, as well as on the leeward side of the island, where there are extensive rice-fields as well as *taro* patches.

The only time we had any ague on board the

ship when she lay in the harbor of Honolulu was when there was an interruption in the trades, and the wind blew from the south over the water. The south wind brings rain and moisture, and epidemics of influenza and tonsillitis prevail at the same time. So remarkable are these winds that the natives have called all the southern districts of the islands "kona," which signifies "sick winds."

Concerning the curative agent of ague, quinine, "it is probable that, beyond its powerful tonic effects, this alkaloid has no preventive influence unless combined with careful protection from damp and chill."

"Although quinine was not found to be a preventive, except possibly in the way of acting as a tonic and rendering the system more able to resist the influence of malaria, it was found invaluable in the cure of the complaint" (Livingstone).

TRANSLATIONS.

COMPLETE GANGRENE OF THE LEFT KIDNEY.—M. Avezou reports the case of a man aged 79 years, who, while under treatment for a left-sided pneumonia, complained of having had for several years pain in the left lumbar region. He had never suffered with nephritic colic, hæmaturia, or difficult micturition; the urine was normal, containing neither albumen nor sugar; and there had never been any œdema of the legs and feet. In eight days the patient died.

The autopsy showed the existence of hepatization of the left with some congestion of the right lung, and a healthy condition of the cardiac valves, though there were some atheromatous patches in the aorta.

The right kidney was of firm consistence, and presented to the eye no alteration. The left kidney, however, was black and friable, and had an offensive smell; the surrounding cellular tissue and the walls of the descending colon at the level of the kidney were also dark-colored, but not at all softened. The ureter of this kidney had a small though permeable calibre, while the renal artery was not obliterated in its terminal portion nor in any of its branches.

On microscopical examination, both kidneys showed plainly the alterations due to interstitial nephritis, with atrophy of a large number of the glomerules, there existing no essential difference between the two organs except in the degree of the pathological change. In some of the tubes colloid casts were found, and in certain parts of the left kidney a very small quantity of granular pigmentary bodies were seen. While the specimens were fresh there were discovered a large number of vibriones and small fatty drops on both kidneys. The microscopist had some doubt as to the real gangrenous nature of these lesions. The spleen was also dark-colored, but the bladder perfectly healthy.—*Le Progrès Médical*. J. B. R.

COMPRESSION OF THE PELVIS BY UTERINE FIBROID.—At a recent meeting of the Société de Chirurgie, M. Guéniot read a report upon this subject apropos of a communication made by M. Here, of Rouen. His conclusions are as follows:

1. Complete and permanent occlusion of the intestine by the compression of a uterine fibroid is, fortunately, of rare occurrence; but the more or less severe troubles produced by this cause, either in the functions of the intra-pelvic nerves or in the excretion of fecal and

urinary matters, appear, on the contrary, to be rather common.

2. Albuminuria and certain grave lesions of the kidneys may be caused by the urinary obstruction.

3. The fibroids which cause the most trouble are not always the largest; those which threaten the greatest danger are the ones which do not rise out of the pelvic cavity.

4. Where compression of the rectum occurs, the gravity of the trouble produced is not entirely due to this cause; other causes combine to render the accident more severe (such are length of accumulation of the fæces, peritonitis, and the formation of peritoneal bands, ulceration of the intestine, atony of the latter from the use of opiates, etc.).

5. Finally, the therapeutics of this affection, heretofore so powerless until recourse is had to enterotomy, are comparatively efficacious when the tumor can be raised out of the pelvic cavity.—*La France Médicale*, 1875, p. 453. X.

INHALATIONS OF WINE OF IPECAC SPRAY IN CATARRH AND ASTHMA.—Drs. Binger and Murrel (*Gaz. Méd. de Paris*, 1875, p. 374; from *Siglo Medico*) recommend this preparation, pure or diluted, according to the susceptibility of the subjects. The first liquid inhalation should be drawn deeply in by the mouth, the tongue being kept down and the nostrils closed. The earlier sittings should be short, with a period of rest between each three or four inspirations. Twenty-five patients have undergone this treatment at the hands of Drs. B. and M., of whom the majority were cured in twelve days, but a few before that time.

The first inhalations are sometimes followed by augmentation of the cough, dryness of the throat, and hoarseness; these symptoms are only temporary. Between the respirations of the spray, gargles should be used to remove particles of ipecac from the pharynx, etc., so that nausea may be avoided. The number of sittings may vary from one to three a day, and the temperature, dilution, etc., may be changed to suit the individual case. X.

TUMOR FORMED BY THE GALL-BLADDER; EXTRACTION OF CALCULI; CURE.—M. Paulet reports the case of a woman of 42, who, in November, 1874, felt a severe pain in the right flank, when examination disclosed the presence of an ill-defined tumor. Suppurating ovaritis was diagnosed. In December it was decided to open the tumor. Vienna paste was applied; a small quantity of liquid escaped. Exploration with the aid of a female catheter showed a number of hard bodies. Forty of these calculi were removed, and the patient had recovered by March, 1875.—*La France Médicale*, 1875, p. 453. X.

VALVULAR LESIONS OF THE HEART IN PHTHISIS.—Dr. Frommolt, in a *résumé* of a number of cases, states, first, that the occurrence of chronic alterations of the heart in conjunction with the existence of phthisis is not so rare as we have heretofore supposed; secondly, that the ventriculo-aortic orifice is more frequently involved than the left auriculo-ventricular opening, though there is really not a very marked difference; and, thirdly, that the simultaneous alteration of several of the cardiac orifices in connection with phthisis is only observed very rarely.—*La France Médicale*. J. B. R.

ANOMALY OF THE POPLITEAL REGION (*Bull. Gén. de Thérap.*, July 30, 1875).—M. Silette reports an anomaly of the internal gastrocnemius muscle of the right leg. Instead of being attached to the condyle of the femur by a single tendon, in this instance it bifurcated and gave passage to the neuro-vascular structures of the popliteal space. J. W. W.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 18, 1875.

EDITORIAL.

ARSENIC IN AGRICULTURE.

THERE is an animal in these parts whose fecundity would satisfy the longings of even the most ultra of that school of social philosophers whose sole creed is "increase and multiply." We refer to the potato-bug. The number of these pests is simply enormous. We have known a tug lying in the middle of the Delaware River, nearly a mile from either shore, to swarm with them; and a friend informs us that after the last northeast storm the beach at Ocean Grove was covered with multitudes, which, apparently, had essayed to cross the Atlantic and had been beaten back.

The only method of meeting the evil efficiently is by the use of Paris green upon the vines; and considerable anxiety has been felt lest the arsenic should be absorbed by the potato, and thereby poison those who used the tuber for food: indeed, one or more of the eminent toxicologists of our country have published warnings against the employment of arsenical preparations in agriculture.

It has always seemed to us very improbable that plants would take up arsenic when strewn on them in the way practised by the farmer. The poison falls chiefly upon the leaves, and these organs do not absorb other substances than gases. The arsenic which reaches the roots is chiefly that which is washed off the vines by the rain. This is a slow process, and consequently the soil is never strongly impregnated with the poison. Only a very small amount can, therefore, reach the roots, and these

absorbents undoubtedly exert to some extent a selective power, taking in that which is necessary for them, and rejecting that which is deleterious.

Experience seems to have confirmed this *a priori* belief in the expediency of using arsenic. The Paris green certainly has been employed during the last two years to an enormous extent, and no well-authenticated case of poisoning has as yet been heard of.

In order to test the matter more fully, a number of experiments have been made. Drs. Snodgrass, Howland, and Brainerd treated beets with Paris green, and afterwards found evidence of the presence of arsenic. We have not seen the details of these experiments, but it is stated that they were performed in such a manner as to leave room for suspicion that the poison was mechanically adherent to the beet. Other more elaborate experiments have yielded a different result. Professor Croft, of University College, Canada, examined the vines and tubers of potatoes which had been completely drenched with Paris green: from the haulms, which could not be thoroughly washed, he obtained a trace of the metal, but in the washed and peeled potatoes not the slightest indication of the poison could be found.

The experiments of Mr. McMurtrie, chemist to the Agricultural Department at Washington, strongly confirm this result. In this investigation Paris green was mixed with soil in such proportion that it represented nine hundred and six pounds to the acre, estimating the depth of soil at one foot. Peas planted in this poisoned ground came to perfection without hindrance, and on chemical examination neither the fruit nor the vines themselves exhibited any signs of the presence of arsenic. Potatoes grown on plants which had been regularly treated with the drug were also submitted to Marsh's test by Mr. McMurtrie, but produced no stain on the porcelain.

The evidence seems to be conclusive; and we think our readers may eat their tubers with an even mind, even though their potatoes have grown in the scourged district.

FACILE EST DESCENSUS IN AVERNO.

MEDICAL teaching in these United States appears to be ever hurrying on towards utter disgrace and ruin. According to a correspondent of the *Clinic*, Indianapolis now has two great medical schools, whose plottings and counter-plottings keep the town agog. The medical department of the

University of Indiana and the College of Physicians and Surgeons, we are told, "divide the empire of Indiana between them,—one reposing grandly on the State of Indiana, one on the proud body of the medical profession of the State." The University is at present ahead: having captured the "Bobbs Free Dispensary," it bobs with it for—students. Alas! every rose has its thorn, and even bobbing its trials. Like the Legislature of Michigan, Mr. Bobbs apparently had a soul above prejudice: the beneficiaries of his charity must be free to choose their method of practice. At least so we infer, because the card of the Bobbs Free Dispensary reads, "Homœopathic physicians will attend all who desire their treatment; cards furnished to such by the clerk." The lion and the lamb,—the fierce regular with lancet and his heroic doses, and the mild disciple of Hahnemann with his diluted moonshine,—hand in hand, hold sweet converse amid the green parterres of the "Bobbs Free Dispensary." Our system daily perfects more and more of its deadly fruits: yet some men still think it a high honor to hold a professorship in a medical college,—that is, to form part and parcel of, and to uphold by word and deed, the existing system of medical teaching in these United States. *O tempora! O mores!*

PATHOLOGICAL EVOLUTION.—In a somewhat remarkable communication, Dr. John Struthers, of Aberdeen, at the recent meeting of the British Association explained how the tendon, say in a rheumatic shoulder, being no longer of any use, was removed from the upper bone and joined on to the lower bone, by which its use was thereby to some extent preserved. The steps of this process were narrated, and the subject was further elucidated by the exhibition of specimens. Adhering to the lower bone by the effects of excited action, the part of the tendon within the joint, having become functionless, was seen in various stages of passing away, while the attachment of the lower bones, on which the muscle pulled, became gradually stronger, till the adaptation was complete. It is very easy to believe that what may occur as a result of causes within the organism, and be therefore pathological, may under other circumstances happen as a physiological change due to causes without the organism.

TO MEDICAL STUDENTS.—Be sure you are starting right. Failure in life very frequently is the result of a man's choosing a calling for which he is not fitted. You may spoil a good business man to make a bad doctor.

LEADING ARTICLES.

THE MECHANICAL TREATMENT OF DISEASES OF THE STOMACH AND INTESTINES.

DURING the past ten years many advances in the treatment of the diseases to which the viscera are subject have been made, the most important of which have been the adoption of methods by which the remedies administered are brought speedily and directly in contact with the diseased portions of the intestine. There has thus been developed a local and mechanical treatment which properly belongs to surgery in its widest sense, but which, apart from the mere instrumental means used, has more to do with internal medicine.

Kussmaul, in 1867, was the first to publish the results which he had attained in the treatment of cases of distention of the stomach by introduction of catheters; by means of which, and a pump, he was enabled to wash out that viscus. In his publications on this subject the methods, objects, and advantages of this mode of treatment were so clearly laid down and explained that those who came after him have had but little to do except to modify some mechanical appliances and confirm his observations. He limited its usefulness very much, saying that in cancerous stenosis or extensive cicatrization of the pylorus, or even when, with but moderate narrowing, the lesions of previous chronic gastritis had caused marked changes, no complete cure could be hoped for, but merely a moderation of the sufferings of the patient.

An important advance was made by Ploss and Jürgensen, who called attention to the principle of the siphon, and suggested its use for the introduction and abstraction of fluids into and from the stomach, in place of the pumps of various kinds which had been previously employed to effect these objects.

The former of these also advised the use of a double catheter, by means of which a continuous stream of water can be passed into the stomach, making its escape via the same instrument, without necessitating any withdrawal of the tube after its first introduction, or any change of pump or turning of valves, as is essential in effecting the same purpose by other appliances.

This method of treatment has now been known about eight years; but, notwithstanding its undeniable usefulness and the warm recommendations which it has received from many clinical observers, its use has never become at all general. This has undoubtedly been to a certain extent due to the fact that too much has been looked for by those who have employed it.

The most simple apparatus with which the stomach can be catheterized, emptied, and irrigated is a rubber tube, two metres in length, nine millimetres in calibre, and with walls two and a half millimetres in thickness.

The introduction of the catheter into the œsophagus is not usually attended with any difficulty, but before the attempt is made a careful inspection of the mouth, pharynx, and chest should be made. It is of especial

importance to look into the condition of the respiratory and circulatory organs, since cases of sudden death consequent upon the introduction of a sound into the œsophagus, while of somewhat rare occurrence in medical annals, are still to be found. Catheterization can be performed either with the ordinary stomach-tube with a lateral orifice, with the double catheter, or, as Oser, of Vienna, prefers, with a simple rubber tube, open at both ends. It is of importance to know about how far the tube should be introduced, for, apart from the danger of injury to parts of the stomach weakened by ulcerative processes, if it is desirable to remove the contents of the organ, unless the tube is thrust far enough into them this purpose cannot, of course, be attained. Measurements to ascertain the average distance from the mouth to the deepest part of the stomach have been made, and in the stomach of a man of middle size, which was moderately dilated, the cardiac orifice was found to be thirty-nine centimetres from the mouth, while when the tube was pushed forward to a distance of fifty centimetres its extremity reached the deepest part of the organ. In some cases where the stomach is distended to a great extent, so that its lower edge is on the level of the umbilicus, or even lower if the abdominal walls are thin, the end of the instrument can be felt, and thus its position accurately determined. In other cases, resort must be had to percussion, and, when the limit is approximately found, the distance from this line to the mouth must be measured, and a corresponding length of the tube inserted.

The stomach, after the introduction of the tube, can, as was said above, be emptied either by a pump or by the siphon. The use of the latter of these methods does away with one source of accident with which the use of the pump may be attended,—namely, the suction of a portion of the mucous lining of the stomach into the tube when the end of this is directly in contact with the walls of the viscus. If due care is taken in managing the suction, no injury need be done in this way; but cases have occurred in which small pieces of the mucous membrane have been torn off, and found in the opening of the catheter upon its withdrawal.

The introduction and withdrawal of fluid by means of the siphon is of the utmost simplicity. The catheter must first be introduced into the stomach, and a tube attached to its free end, when both are to be filled with water, and the free end of the rubber tube brought to a level which is lower than that of the fluids of the stomach, when they will flow out, unless some solid matter plugs the tube so firmly that the current of fluid in the siphon cannot move it. This mode of procedure on the cadaver has demonstrated that it is perfectly feasible to withdraw almost all the contents of the stomach. The pump can be combined with the siphon and used until a stream is started through the tube, when, if the orifice of escape is lowered, the stream will continue to flow. If it is desirable to irrigate the stomach, in other words, first to introduce fluid and then withdraw it, the same method is used; the only modification being that the free end of the tube must

be kept at a higher level than that of the contents of the stomach while fluid is entering, and must be lowered again when it is desired to cause the direction of the current to change.

If the double catheter, which consists of a rubber tube which is divided down its entire length by a partition, is used, of course some time will be saved, for no changes in the manipulation will be required, and the current will flow uninterruptedly. The amount of fluid which can be introduced into the stomach differs, of course, with its capacity. Experiments upon cadavers have shown that it is a difficult matter to decide, since stomachs which would all be said to be of normal size differ very considerably. If it is desirable to do so, the water can be medicated before it is passed into the stomach, and various astringents, disinfectants, and other drugs have been thus used. The advantages in a diagnostic point of view of this introduction of fluid into the stomach deserve mention, for in some cases of internal tumors, as to whose character and location there is doubt, the exact definition of the area of the stomach is of material aid in determining their seat. In the treatment of cases of poisoning, when the poison swallowed is not of a caustic nature, the “*bougie à double courant*” affords a speedy and ready method of removing the contents of the stomach, and forms a valuable addition to other modes of life-saving apparatus. Cases of this kind, unfortunately, are not usually seen soon enough for successful treatment, and the great practical value of irrigation is in the treatment of certain affections of the stomach. If the object is simply to remove the contents of the stomach soon after a meal, it is better to administer an emetic, for the remains of the food will be apt to choke the tube and stop the flow of liquids. In that frequent form of dyspepsia in which there is a sense of weight in the region of the stomach after eating, bad taste, eructation, giddiness, etc., more good can be obtained by strict diet and attention to other hygienic measures than by this mode of treatment. But in those forms of chronic catarrhs which are attended with enlargement of the stomach and a marked increase of the secretion of mucus, and in those of a torpid character in which a healthy reaction was awakened, irrigation of the stomach was attended with good results. In some of these the mucous secretion forms a coating which mechanically interferes with digestion, and its removal by frequent washings is attended with great improvement in the performance of this function. The existence of perforating ulcer of the stomach should be regarded as a contra-indication to this mode of treatment, but in cancerous obstruction of the pylorus, if there is no hemorrhage, irrigation can be employed, and is often attended with considerable relief.

Simon has done for the mechanical treatment of some diseases of the intestine what Kussmaul did for those of the stomach. He introduced a tube five feet in length into the rectum, and by means of forced injections of water reached the descending colon, although Wachsmuth asserted in 1862 that with a similar tube he

had reached the ileo-cæcal valve. Hegar suggested a much simpler mode for the administration of injections of this character. He placed the patient in the knee-elbow position, and permitted water with a head of one to one and a half feet to flow through a rubber tube into the intestine. Mosler placed his patients on their backs and allowed large quantities of water, even up to five litres, to flow into the gut, and in cases of obstipation, helminthiasis, and also of catarrh of the small intestine, obtained good results. The question as to whether fluid can be in this way introduced into the small intestine cannot be certainly settled by experiments upon the dead body, since the peristaltic motion which may play an important part is here done away with. In the experiments which Oser made to determine this point, in only one instance did he discover that any fluid passed, and all the tests which he made by the introduction of the sulphocyanide of potassium above the valve, and the chloride of iron below, gave negative results. These experiments showed, however, that fluids would reach the higher portion of the large intestine before the lower part is entirely filled, and that the air which is present in the gut cannot be entirely expelled, but remains and distends some portions more than others as the peritoneal attachments are more or less firm. The same was shown by a patient with very lax abdominal parietes, in whom all the structures of the pelvis could be made out by palpation. After only one litre of water had been injected with a head of four or five feet into the rectum while the patient was lying on his back, its presence in the cæcum could be distinctly made out, while the descending colon was but little distended. The irrigation of the large intestine in the living is very simple, and requires no apparatus but a tube four or five feet long, with a stopcock on one end, and a short tube to go into the intestine. If the sphincter is not in good condition, and does not contract tightly around the tube, an obturator made of rubber is also needed to prevent the escape of the injection by the anus. But little pressure should be used at the commencement of the injection; but by elevating the vessel containing the fluid it may be gradually increased, but should be at once diminished if the patient complain of an undue sense of tension or pain. As in the stomach, so also in the intestine the introduction of large quantities of water may be of value either in a diagnostic or a therapeutic point of view. The situation of the large intestine relatively to that of the small intestine is very constant, and when it is filled over its area there is a dulness which forms a good starting-point for determining the situation of other normal or pathological contents of the abdomen.

When incarceration of the gut exists, by the injection of large quantities of water such a strain may be brought to bear upon the incarcerated portion that it may be restored to its normal position. If the incarceration should be at some point in the course of the small intestine, although the water which is injected does not itself pass the valve it is possible that, by the compression of gas before it, it may exert a favorable

action. Oser has himself seen no good results from this mode of treatment in incarcerated hernia, but other authorities have reported them, and before operating it may be advisable to make an effort at the reposition of the gut by intestinal irrigation. The inflammatory affections of the mucous membrane of the large intestine offer the most fruitful field for local treatment. Dysentery, follicular ulceration, catarrh, typhlitis in its early stages, and proctitis can be much more safely and rationally treated in this way, since the remedial agents are brought directly into relation with the diseased tracts. The surface of the intestine can thus be treated as an open wound, and all fecal matters as well as irritating discharges can be readily and frequently removed.

The more usual astringents can be used in this way, and, with the exception of zinc, carbolic acid, and nitrate of silver, in the strength in which they are commonly applied locally; but, as there is some absorption, it is well to give those which are poisonous in small quantities.

Mosler advises the use of this method in diseases of the small intestine, and claims that he has thus obtained good results; but if fluid does pass the ileo-cæcal valve, it can only be by its injection in such quantities as to cause great tension of the large intestine, and at best but the lower part of the ileum will receive it. If good results are thus attained, it is more probable that they are to be attributed to the absorption of the remedies and their action upon the secretion and peristaltic movement of the intestine.

CORRESPONDENCE.

LONDON HOSPITALS AND MEDICAL SCHOOLS.

LONDON, August 9, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—During my sojourn in the metropolis I have visited a number of the hospitals, and have gained some information which may perhaps be interesting to your readers. The number of hospitals in London is legion; but there are three or four that are especially prominent, either from their size or from the reputation of the medical men associated with them. One of the oldest is St. Bartholomew's, which, founded in 1123, has increased its facilities for treating persons "infected with divers great and horrible sicknesses and diseases," until it now contains seven hundred and ten beds, and has connected with it a secondary hospital for convalescents, and a medical school which claims to have more students than any other in London. To show the work done by this one institution, I may state that in some years there have been consumed as much as seven hundred gallons of cod-liver oil, eight hundred pounds of castor oil, twelve hundred pounds of salts; the last-named drugs indicating, one would think, a condition of constipation quite appalling. Such names as Harvey, Percival Pott, Abernethy,

and Paget may well add lustre to this charity of nearly eight centuries.

The finest hospital, architecturally considered, is certainly the new St. Thomas's. This, situated on the south side of the Thames, directly opposite the Parliament Houses, consists of six four-story brick buildings, placed one hundred and twenty-five feet apart, and connected by corridors. It was completed in 1871, at a cost of £500,000, and opened for the reception of patients in June of that year. It is truly a beautiful structure, but it is a question whether the money expended in mere architectural display might not have been employed more advantageously. St. Thomas's also has a medical school; among the lecturers being Dr. Murchison, on medicine; Dr. Barnes, on midwifery; Mr. MacCormac,—who was associated with Dr. Sims, of New York, in the ambulance service during the Franco-German war,—on surgery; and Mr. Liebreich, on ophthalmic surgery.

Guy's is another noted London hospital, accommodating six hundred and ninety patients, and containing a very fine museum of normal and pathological anatomy, as well as one devoted to comparative anatomy. In the chapel of the hospital lie the remains of Sir Astley Cooper, who was buried there at his own request.

Among the smaller institutions may be mentioned University College Hospital, with its long list of names familiar on both sides of the Atlantic; for who has not heard of Sir William Jenner, Reynolds, Sidney Ringer, Tilbury Fox, Erichsen, Berkeley Hill, and Heath? Sir Henry Thompson has but recently resigned his position on the staff of this hospital.

King's College Hospital is small, but can boast of such men as Watson, Beale, Fergusson, and Soelberg Wells. Of the special hospitals the Royal London Ophthalmic Hospital, Moorfields, is perhaps the most important.

A feature in these London hospitals, and a good feature it is, is the almost universal employment of women nurses in the male as well as in the female wards. They certainly make better and more gentle attendants on the sick than men, and the neatness of the wards fully attests the presence of woman. They wear small white caps, and their modest dress and demeanor as they stepped from one patient to another struck me most forcibly. Some of the hospitals have training-schools where these nurses are instructed in the various duties to devolve upon them when placed in the wards. In Philadelphia there exists a somewhat similar institution, where monthly nurses are given instruction to fit them for the lying-in room; but why do we not attach the same importance to the proper training of all nurses? Are not those who attend the patient continually as necessary to his welfare as the practitioner who sees him but once or twice during the day?

The general arrangements of the hospitals of London seem to be much the same as with us, but on the whole I think their wards lack the cheerful aspect that charac-

terizes ours. An exception, however, must be made in favor of the well-waxed floors, which are less likely to harbor germs of disease than ordinary floors, the chinks and cracks of which must retain many particles of dirt notwithstanding the most vigorous sweeping and cleaning.

Clinical lectures on surgery are delivered in the hospitals several times during the week; but how different they are from American hospital clinics, where we see classes of three hundred to four hundred students assembled in spacious amphitheatres! Here the classes are very small, as must needs be, since they consist only of the students of each respective hospital. The lecture-room does not contain seats, but is arranged in a series of ascending steps, on the edge of which is fastened a railing four feet high; upon this the *standing* student leans while watching the operator. I was going to say lecturer, but it would scarcely be correct to apply that term to one who says so little. This is the programme:—the patient is brought into the arena and placed on the table; the surgeon enters, perhaps fifteen or twenty minutes late; states the disease and the operation proposed; and then goes on with it to completion without saying a word. There is no discussion of differential diagnosis, the various modes of operating, or the regional anatomy; and consequently the student sees merely the cutting and suturing, and, if a first-course man, learns nothing.

So much for English clinics, which are far inferior to our own; but the training in the hospital medical schools seems, on the contrary, to be very thorough. Besides the seven regular branches, the curriculum embraces lectures and instruction in pathology, both didactically and in the post-mortem room, botany, practical physiology, practical chemistry, and dental surgery. In addition, the pupils have the opportunity of obtaining much clinical experience by filling the positions of dressers, clinical assistants, and, finally, of house physicians and surgeons. In this way not only does the student gain a practical knowledge of his profession, but the hospital wards come under the supervision of men who have been trained for the higher positions by a period of probation in the lower.

Although the student is instructed in some hospital school, he does not obtain his diploma therefrom, but, having studied for four years, and having passed a preliminary examination in arts, which is absolutely essential, he applies to the University of London, the Royal College of Physicians, the Royal College of Surgeons, or the Society of Apothecaries, for examination and a license to practise. The University of London is the only examining body in the city which confers the degrees of Bachelor of Medicine, Bachelor of Surgery, Doctor of Medicine, and Master in Surgery; the others giving merely licenses to practise, diplomas of membership, etc. The preliminary examination in arts spoken of above embraces the ordinary English branches, chemistry, Latin, and, sometimes, Greek. By this method the standard of scholarship is placed higher, and no man is allowed to practise medicine who does

not possess ordinary scientific knowledge. The degrees of Doctor of Medicine and Master in Surgery are conferred upon those who, after five additional years of study and practice, are found capable of passing the requisite examination. Thus you see that doctors are much less easily made in England than in America; and it is easy to understand the ready sale of bogus diplomas in the former country.

JOHN B. ROBERTS.

NEW YORK, September 7, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The dulness of the long summer vacation still seems to be over everything here; but already the early notes of preparation have begun to be heard in our midst, and there are not wanting indications to show that in another fortnight the medical world, like the rest of human kind, will have become roused to its accustomed activity.

Most of our prominent practitioners have already returned to town, or will do so very shortly; though Professors Sands and Fordyce Barker and others who have been abroad for the summer are not expected back until a little later.

By those who have been away for any length of time, some changes will be noticed about the city. The new building of the Medical Department of the University of New York, situated at the foot of East Twenty-sixth Street, in the immediate vicinity of the old college, has been rapidly pushed forward to completion, and now stands ready for occupancy.

It is of brick, with handsome brown-stone facings, and is a substantial and capacious structure, though architecturally quite inferior to the new buildings of the Medical Department of the University of Pennsylvania. The arrangement of the interior, however, is very admirable, and its appointments will, no doubt, be the most complete of any medical college in New York.

Work has also been steadily progressing on the new building of the New York Hospital Society, on Fifteenth Street near Fifth Avenue, and the first story is now up. The hospital will be about one hundred and fifty feet long by one hundred feet deep, and its estimated cost when completed and furnished, exclusive of the price of the land, is four hundred and thirty-five thousand dollars.

This building is being constructed in accordance with the plan for the resumption of hospital operations suggested by a special committee of the Board of Governors appointed to report upon a site for hospital buildings, and the general principles which should control the Board in its selection and in the construction of the necessary buildings.

The recommendations of the committee, the conclusions of whose report received the unanimous approval of the Governors, are based upon the following facts:

1. That additional large general hospitals are not at present required in the city of New York, the accom-

modations of such existing institutions, with the exception of Bellevue, being largely in excess of their use by the sick poor; and that the failure of this class to avail themselves of the superior privileges of these institutions arises from the inability of the poor to pay the very moderate hospital charges for their treatment and support while patients, and the insufficiency of means of the hospitals to support more than a very limited number of free patients.

2. That the concurrent testimony of all conversant with the requirements of the city south of Twenty-third Street establishes the fact that there is pressing need in that locality of hospital accommodations for the immediate relief of sufferers from accident and sudden acute sickness.

3. That small hospitals, with twelve beds each, a resident physician and surgeon, two nurses, and the necessary subordinates, established at proper distances, could be conducted at a comparatively small expense, relieving all applicants from a prescribed locality, and, if need be, accommodating such as could not be immediately moved, until able to be transferred without risk to a general hospital.

4. That the Society of the New York Hospital is now in a position to inaugurate such a system of hospital treatment, and that no more economical and beneficial application of its funds can be made at the present time.

5. That a central establishment, having also accommodations for the executive officers of the Society, the hospital library, pathological cabinet, and for the meetings of the Board of Governors, is essential to the prosecution of the system of relief indicated.

In accordance with these views, the Society purchased five lots on Sixteenth Street, including the old Thorne Mansion, a handsome brown-stone building, with ample room for the library, pathological cabinet, and executive officers, and also a number of lots immediately in the rear, on Fifteenth Street, upon which the new hospital building is now being erected. The cost of this property amounted in all to three hundred and fifteen thousand dollars.

Early in the summer the first of the small branch hospitals was opened down town, in the vicinity of the City Hall, the Society having obtained from the city the use of a building which was formerly, we believe, a precinct station-house; and since then it has been doing excellent service in the reception of accident and emergency cases.

Until October last the use of the New York Hospital Library had been confined to the physicians and surgeons on the staff of the hospital and the annual subscribers, and the library was open for consultation only a few hours daily. Since its removal to the spacious rooms in the building on Sixteenth Street, however, it has been made free to all, and the hours of admission have been extended so that it is open daily for consultation from 10 A.M. to 10 P.M., with two brief intermissions, while the profession have shown an increasing appreciation of the privileges thus afforded them. In

the extent of its collection this library is second only to that of the Surgeon-General's office, Washington, and that of the Pennsylvania Hospital, Philadelphia. At the beginning of the present year it contained nine thousand six hundred and forty-five volumes, three hundred and thirty of which had been added during 1874.

The pathological cabinet is also in a flourishing condition, and has recently received quite a liberal endowment from Mr. Robert Ray.

Our grand new post-office was occupied for the first time last week, and thus far only two sources of dissatisfaction in regard to it have manifested themselves, —viz., a pie-stand desecrating its massive corridors, and the lack of ventilation in the basement. The first of these nuisances has already been abated by the prompt interference of the Postmaster-General himself, and it is to be hoped that the other abuse will also soon be corrected. It is gratifying to hear that ventilation has at last come to be considered a very important element in the construction of every new building, and every accomplished architect is at least supposed to be thoroughly acquainted with the subject; though, alas, how seldom it is that we meet with any much-frequented edifice in which there is a constant supply of pure, fresh air!

Of churches, that of the Rev. Dr. John Hall, now approaching completion at the corner of Fifth Avenue and Fifty-fifth Street, will, without doubt, be the most completely ventilated of any on this continent, if the elaborate system designed by the architect (who was also the architect of Roosevelt Hospital) can be successfully carried out. The interior of the building was really finished last spring, but it will be necessary to see how the ventilation stands the test of the winter season before judgment can be finally passed upon it. This church is one of the largest in the city, costing, it is said, over a million of dollars altogether. The auditorium is one hundred feet deep on the main floor, one hundred and thirty-six feet deep on the gallery, eighty-five feet wide, and sixty feet high, with seats for two thousand persons. It has been the aim of the architect to produce a building which should be as perfect as possible as to facilities for hearing and seeing, and to secure for each listener the utmost comfort in respect to such matters as heating and lighting, as well as ventilation.

There are twenty-four large and twenty-four small windows. Each window has two sets of sashes, glazed, with stained glass, and with gas-jets between them. The space between the two sashes is a large ventilating flue, drawing the air from the church through the perforated panels of the wainscoting, the current being increased by the heat of the gas-burners within the space. Every gas-burner in the church is hidden by ornamental glass-work, giving a mellow light which is most grateful to the eye, and is also supplied with ventilating flues.

An air-tower at one corner of the building supplies pure air, which is drawn by a fan in the cellar, at the

base of the tower, that is worked by a ten-horse-power steam-engine. Ten feet above the floor of the tower, inside, a perforated water-pipe extends around the walls, making a shower to cool the air in the summer, and free it from dust, if necessary. The entire cellar floor can also be sprinkled to cool the air. The fan is of iron, seven feet in diameter, and can make two hundred and twenty revolutions in a minute, forcing thirty thousand cubic feet of pure air into the church during that time. The entire cellar is an air and heating chamber, into which the fan delivers the air, the ceiling being covered with a net-work of steam-heating-pipes.

Before the air enters the auditorium, it passes over the steam-pipes, and is warmed. The warm air enters the body of the church through movable slats in every pew, and every person in the pews can have warm or cold air at his feet, as he chooses. When cold air is forced into the auditorium, it enters fifty feet above the heads of the congregation, so that there can be no draught. The steam for heating is generated in two fifty-horse-power boilers.

The public schools reopened yesterday, and there is reason to fear that they will now be more overcrowded than ever, on account of the enforcement of the Compulsory Education Act. Few, if any, of our school-houses are scientifically and adequately ventilated, and there can be no doubt that the health of many of the children is perceptibly affected in consequence. There are other evils also, besides the lack of ventilation, which seem, unfortunately, only too prevalent even under the best systems of common education, and yet which could be very easily remedied. In Germany the increase of myopia among school-children has been shown to depend in great part on badly-lighted study-rooms, unsuitable seats and desks, too long continuous hours of study, and a confined range of vision. Examinations of schools in Europe in order to determine the refractions of scholars' eyes have of late years been of quite frequent occurrence; and in imitation of the labors of Jager, Cohn of Breslau, Erismann and Dobrowsky of St. Petersburg, Hofman of Wiesbaden, and other European oculists, Dr. Callan, of this city, Assistant-Surgeon to the New York Eye and Ear Infirmary, conducted during last spring and the early summer a series of examinations on the eyes of school-children here. For this purpose he selected pupils from the colored schools, and for the following reasons. Heretofore nearly all the examinations have been made in Germany, and, needless to remark, on whites. It is, to most, familiar that there is a very large percentage of myopia among the students in the gymnasiums and universities there. The Germans acquire myopia by their long years of study, having perhaps inherited a predisposition to it, or inherited it already developed. Our colored brethren, as a rule, never did enjoy a thorough system of education. The present generation in New York may be said to enjoy as thorough as the city affords; but their forefathers did not. Neither have they been raised to such pursuits as demand a very close application of the eye, such as engraving, etc.,

and therefore, *ceteris paribus*, the negro's eye should approach nearest to a natural eye, *i.e.*, the normal eye. The very best material for examinations of this kind could be obtained in the Southern States, where, until of late years, the negro was unjustly debarred from the luxury of spoiling his eyes in the attainment of a modern education.

In these examinations each scholar was placed thirty feet distant from test-types (Snellen's) on the wall of the study-room, and each eye alternately tested on card "A," for example, the result being noted. Then convex and concave glasses were placed in turn before each eye, and the pupil was asked to read card "E." "Cohn was very fortunate," says Dr. Callan, "in being able to examine two hundred and forty scholars' eyes under the influence of sulphate of atropia, an opportunity that does not present itself very often; and such a procedure was entirely out of the question in the present instance, particularly as the colored children feared from the first that their eyes were, by a species of legerdemain, to be taken out and then replaced,—a belief, by the way, which is not confined to colored children, but is also shared by some very large children of the Caucasian race. Not being able to put atropia into the scholars' eyes, we put it in our own, so as thoroughly to paralyze the action of the ciliary muscle, and kept our eyes in that condition during the ophthalmoscopic examinations. Each scholar's eyes were separately examined with the ophthalmoscope in the upright image, and the correcting-glass, used to view the fundus distinctly, gave the refractive condition of the examined eyes. In this manner the examination was made with all due accuracy. Our eyes being under the influence of atropia, we were not able to use our accommodation, and the glass used to see the fundus gave the desired refraction."

The ophthalmoscopic examinations were made in the forenoon, and extended over a period of five weeks, during which time both eyes of the examiner were under the influence of a four-grain solution of sulphate of atropia applied three times daily, so as completely to paralyze the accommodation. Two public schools were examined, both together containing 457 scholars. The following is the result of the examination: 431 emmetropic, 94 per cent.; 12 myopic, 2.6 per cent.; 14 amblyopic, 3 per cent.

Public School No. 3 contained 293 scholars; 274 emmetropes, 10 myopes, 9 amblyopes.

Public School No. 4 contained 163 scholars; 156 emmetropes, 2 myopes, 5 amblyopes.

School No. 3 had a percentage of 3.4 per cent. myopes, while School No. 4 had only 1.2 per cent. myopes. The explanation is that School No. 4 has only a local attendance, while School No. 3, which has an excellent corps of teachers, and is really the colored high school, is frequented, in consequence of its superior advantages, by children of well-to-do parents from all parts of the city proper, as well as Manhattanville and Harlem.

Dr. Callan is fully satisfied that, had he examined an

equal number of white scholars, a much larger percentage of myopia would have been shown than that found among the colored children, *viz.*, 2.6 per cent.

The effect of the recent high temperature on the mortality of the city is seen in the fact that 674 deaths were reported during last week, against 592 reported the week previous, when the weather was cool. The extra corps of vaccinators have still continued their work, and during the month of August made over ten thousand vaccinations. As a direct result, we find smallpox steadily diminishing, and during the week ending August 28 there were only twenty-six cases reported. For the same week, the number of cases of diphtheria ran down to thirty-nine; the disease causing but twenty-three deaths, the least number of any week in the year. Smallpox caused fourteen deaths during the last two weeks of August,—also the least number of any fortnight in the year. The Registrar of Vital Statistics reports that in the week ending August 28 there were thirty-four deaths from bronchitis and pneumonia, thirty-nine in the previous week, thirty-four in the second and forty in the first week in August, and that in these four weeks the least mortality in the year was registered from these two diseases; so that we have some offset at least to the increased infant mortality from diarrhoeal maladies.

PERTINAX.

REVIEWS AND BOOK NOTICES.

CANTHOPLASTY AS A REMEDY IN CERTAIN DISEASES OF THE EYE. By C. R. AGNEW, M.D. New York, 1875.

This pamphlet of only ten pages is a brief but clear statement of the conditions which, in the author's experience, have been benefited by canthoplasty. It is stated to be of great therapeutic value, especially in cases of recurring strumous ophthalmia which have proved rebellious to general therapeutic measures. In one hundred and ninety-one cases tabulated on the tenth page, it seems, however, to have been employed quite as frequently in conditions not necessarily strumous, but in which the general indication of relieving the cornea from undue pressure or unfavorable contact with the lids was presented,—*e.g.*, in granular lids, pannus, keratitis, ulcerative or not, distortions of the lids, blepharospasm, and panophthalmitis. The author's method of performing the operation is very carefully stated, the description being aided by five illustrations on wood. His method differs from that usually employed only in his care to divide the upper tarsal ligament. That Dr. Agnew recommends it is much in its favor, and will secure for canthoplasty a trial by those not already in the habit of employing it.

OTITIS. By C. R. AGNEW, M.D. A Lecture extracted from the series of American Clinical Lectures.

In this very readable pamphlet, Dr. Agnew sets forth in plain language (not for experts, but for the general practitioner) the dangers of relying upon ordinary antiphlogistic measures in the treatment of acute inflammatory conditions of the outer and middle ears. He directs attention to the necessity of early incisions and repeated leechings and inflation of the middle ear. He advises in cases of measles and scarlet fever that the ear be examined daily. The lecture is preceded by a dissertation of a somewhat elaborate character,—more

valuable to the layman, we should judge, than to the physician,—“on taking cold.” Dr. Agnew is an advocate of total abstinence as a preventive of “taking cold,” and strongly advances the claims of coarse farinaceous food, such as wheaten grits. Of the latter he says, “Their mechanical contact with the digestive organs does for them a work something like that which friction of the skin with the ‘hair mittens’ does for the surface of the body in hastening the desquamation of effete and sickly epithelium and the cleansing of follicles.”

MANUAL OF COMPARATIVE ANATOMY AND PHYSIOLOGY.

By S. MESSENGER BRADLEY. Third Edition. Lindsay & Blakiston, 1875. Pp. 262, 12mo.

This little volume presents a faithful exposition of the subjects treated of under the above title. As can be inferred from the size of the volume, the matter is compressed, the style employed not permitting any other than the most succinct statement of facts. The work is designed especially for preparing English students for their examinations. We are therefore prepared to see the chapters on the vertebrata very full; indeed, they occupy the latter half of the volume. The illustrations are not of the highest order of excellence, but, in a work of so little pretension, this is, after all, no great defect.

GLEANINGS FROM OUR EXCHANGES.

MERCURIAL BATHS IN SYPHILIS (*The Lancet*, August 21, 1875).—Mr. Henry Lee describes as follows the plan of administering the mercurial vapor-bath, which he extols highly as comprising, in many respects, the greatest therapeutic advantage with the least possibility of unpleasant effect.

A lamp, in which the methylated spirits of wine is burned, is put into a case, made principally of wire gauze, on the principle of the Davy safety-lamp. The top of the case is fitted with a central, movable, small circular plate, surrounded by a trough, which should contain one ounce of water only. The water should be boiling when first put in, or should be allowed to remain over the lighted lamp until it begins to boil. Thirty grains of re-sublimed calomel are then spread out on the central small circular plate. This should be quite dry. The patient then sits, without his clothes, on a small stool or chair, and the lamp is placed between his legs. A cloak made of moleskin or of some thick material is then made to cover the whole apparatus, and is tied round the patient's neck. It is important that the cloak should go quite down to the ground all the way around. As the water boils, a certain quantity of steam is enclosed within the cloak, and a little later the vapor of the calomel as it rises passes through the steam and becomes mixed with it. The water first disappears, and the calomel is sublimed in from ten to fifteen minutes. The patient then gets into bed with the cloak on, so as to make it his night-dress. In this way the calomel is necessarily kept on the surface of the skin. The cloak used is furnished with a cane hoop, so as to be kept away from the skin during the action of the bath, and this hoop may be removed as soon as the bath is over, and replaced again before the bath is used the next night. The cloak has a slit in front, which the patient is generally directed to open for about an inch, so as to allow some of the vapor to escape. This rises in front of his mouth and nose, and he is directed to inhale it for a minute at the expiration of each five minutes during the continuance of the bath, so as to breathe the vapor for about three minutes altogether. The patient during this time keeps his head up, so that the moistened calomel vapor passes for about six inches through the

common air before it is inhaled. This inhalation is not always necessary, but it furnishes a means of regulating with the greatest nicety the action of the mercury, as indicated by its effects upon the gums. He has never found mercury administered in this way produce salivation where patients had not also taken it in some other form. The action is upon the surface of the body, and the internal parts are comparatively unaffected. No diarrhoea is produced except from some accidental cause. The stomach and intestines are not irritated, and are free for the use of food or medicine. The perspiration produced amounts only to a slight moisture on the skin, and when this is the case the patient very rarely experiences any debilitating effects from the continued use of the bath. During this treatment Dr. L. generally recommends patients to abstain from taking vegetable acids; and for this purpose, as a rule, they are told not to eat raw vegetables or raw fruits, such as salads, cucumbers, celery, apples, pears, and oranges. As the object is to have the calomel in contact with the skin, the patient washes only as much as may be necessary.

NITRITE OF AMYL IN SEA-SICKNESS (*The Lancet*, August 21, 1875).—Dr. Crochley Clapham, believing the proximate cause of sea-sickness to be an undue congestion of the vessels of the spinal cord, has tried to remedy this condition by the use of nitrite of amyl in one hundred and twenty-four cases; one hundred and twenty-one of which proved eminently satisfactory, there being no return of the malady after the administration of the nitrite. The remaining three cases were only unsuccessful in so far as they required a further dose or two of the remedy.

The mode he adopts of exhibiting the drug is by inhalation, three drops of the nitrite being poured on a handkerchief and held *close* to the patient's nose. The inhalation must be conducted rapidly, so as to give the full influence to the drug without a *too free* admixture of air.

The action of the remedy in freeing the circulation and relieving the hyperæmia of the spinal cord will be quickly evidenced by a throbbing sensation in the temples (occasionally rather disagreeable), and by a more or less general flushing and increased warmth of the surface of the body. This warm and comfortable glow, which takes the place of the chilly sweat so disagreeable in this disease, is usually followed in the course of half an hour by a pleasant slumber, from which the patient wakes to eat a hearty meal. Should the sickness recur, which it may do after the lapse of twenty-four hours, the inhalation must be repeated. The patient should be in bed when under treatment, so as not to interfere with the subsequent sleep; and it is usually better to allow one fit of vomiting to take place before applying the remedy, not only to insure the *bonâ fide* character of the seizure, but also because it is advantageous unless the patient be in a very weak state of health. He met with only one case in which the medicine was refused on account of disagreeable effects, and in this instance, which occurred in the tropics, the patient complained that “it made him feel so hot he would rather be sea-sick.”

CASE OF DISLOCATION OF THE ASTRAGALUS (*The Boston Medical and Surgical Journal*, August 26, 1875).—Dr. David W. Cheever reports the case of a man who fell about twelve feet, alighting on his feet, and injuring the left foot severely. There was no distortion, crepitus, or mobility above the ankle. Both malleoli were in place, and firm. There was a bony crepitus at the neck of the astragalus. There was a very marked, partly rounded, and partly sharp projection of bone between the inner malleolus and the heel. There was a depression beneath the outer malleolus. The rest of the

tarsus and metatarsus seemed normal. The tendo Achillis was drawn tense, and shortened, over the unnatural prominence of bone which lay between the inner ankle and the heel. The heel was drawn up. The mobility of the ankle-joint was largely diminished. The last joint of the great toe was strongly and immovably flexed at a right angle.

The diagnosis was a fracture of the astragalus at its neck, and a dislocation of the whole body of the astragalus from between the malleoli and os calcis, inwards and backwards.

Attempts were made with extension and counter-extension, and by alternately flexing and extending the foot, to press the bone back into its place, but without any effect. Tenotomy of the tendo Achillis, the tibialis anticus, the tibialis posticus, and the flexor longus digitorum was then resorted to, but also unsuccessfully. The foot was then secured immovably in a carved outside Pott's splint, and the leg laid upon its outer side. The tenotomy punctures were covered with plaster, and the joint and dislocation dressed with a lotion of equal parts of laudanum and cold water. Ulceration and sloughing took place, but there was no abscess, caries, or necrosis, and the patient recovered with a tolerably useful foot.

A CASE OF POPLITEAL ANEURISM CURED BY AN EXTEMPORIZED COMPRESSOR (*The Lancet*, August 21, 1875).—Mr. Nathaniel Alcock reports a case of popliteal aneurism occurring in a woman, æt. 38, and in which treatment by means of Carte's tourniquet and flexion had proved unavailing. It was remembered that Dr. Bellingham had found the weight of a conical piece of lead to be borne when no instrument would be submitted to. A tin funnel was procured, and a cork inserted into the narrow end and covered with a soft pad. The funnel was then filled with shot, and the whole enclosed in a calico bag to prevent the shot from escaping. The funnel was then placed over the femoral at the fold of the groin, the exact position of the vessel being indicated by a piece of soap-plaster, spread on leather, pasted over it, and additional shot was poured into the bag until the circulation was completely stopped; the limb was unbent to relieve the acute pain in front of the knee, and the weight was held in this position for twelve hours and a half without the slightest variation. At the end of that time all pulsation in the tumor was at an end, and the aneurism was cured.

For two days the funnel was applied for a few hours each day to secure the full contraction of the clot, and then was finally omitted. The total weight of the loaded funnel was six pounds two ounces.

The collateral circulation was so effectually developed that the temperature of the limb was not at any time perceptibly lowered, nor has any inconvenience arisen from occlusion of the main artery. The tumor was reduced to the size of a small walnut, and is perfectly solid.

TETANUS FOLLOWING MENORRHAGIA WITH PURPURA HÆMORRHAGICA—HYPODERMIC INJECTION OF CHLORAL—CURE (*The Obstetrical Journal*, August, 1875).—Dr. Ribell relates the case of a patient, æt. 36, who suffered from purpura hæmorrhagica after each of her four confinements. Nine weeks after her last one, severe rigors set in, followed by contraction of the muscles of the neck, stiffness, and difficulty in deglutition, with slight trismus. The symptoms increased rapidly, and left no doubt as to their nature. Fifteen-grain doses of chloral every half-hour were given for three hours, when sleep supervened, and lasted five hours. The symptoms returned when the patient awoke, and gradually increased in severity, pains in the back and suffocation being complained of. Thirty grains of chloral in solution were injected into the side of the

neck, and repeated every hour for six hours. Sleep then occurred, and lasted nine hours, the patient awakening free from all symptoms. Two hundred and ten grains in all were injected. Convalescence was slow.

BLINDNESS AND DEAFNESS DUE TO TAPE-WORM (*Boston Medical and Surgical Journal*, August 19, 1875).—Dr. Williams reports the case of a child of eight years, puny but in fair health. It had suddenly lost its hearing six weeks previously. Four weeks before, that is, a fortnight after the deafness, it had in one day lost its sight. For a day blindness was complete; then for a time there occurred successive intervals of sight and blindness. If any one whom the child knew brought his eyes close to it, it would catch the expression of the eyes and show recognition, but it recognized no other light, however bright. The ophthalmoscope showed no local trouble or cerebral lesion. There were signs of tape-worm present, and the loss of the two functions could be attributed only to reflex action. There had been no vomiting. On the removal of the worm both sight and hearing completely returned.

MISCELLANY.

MEDICINE IN INDIA IN THE OLDEN TIME.—Meanwhile, we are grilling in India, where two hundred years ago there were no physicians, excepting those attached to royalty, the poor people consigned to herbalists. When a potentate had megrims, neuralgia, or headache after salmon, he was bled in four places under the tongue to the extent of eight ounces, received into four golden porringers. The queen's tongue could only be seen protruded through a curtain, her royal pulse felt through lawn, whilst for venesection a jewelled, well-turned, shapely arm would just peep through silken or velvet hangings of crimson, purple, green, and gold, the rest of the body concealed behind the arras. One grandee had ten Persian physicians, the senior a man of jealous temperament, who threw his pretty wife over the castle battlements to cure her of flirting. The lady only broke her ribs. The indignant public cried shame unto him; so the physician, packing up goods, chattels, and wounded wife, sold his practice and left the place. He had not travelled far when the monarch, taken ill, probably from delirium tremens, ordered his recall. Promptly stabbing wife, four children, and thirteen female slaves, by way of standing up for professional dignity, the doctor returned to work, resuming brass plate and night-bell, probably publishing the whole correspondence in the *Delhi Medical Gazette* under the head of ethics.

These physicians, cognizant of Ganges water causing diarrhœa, always praised wells in preference; and in the history of every nation, from the earliest records, the water theory, under the designation of poisoned wells, stands prominent also. So far back as the days of Plutarch the operation for laryngotomy was performed when a fish-bone stuck in the throat. Aurungzebe, of Delhi boil celebrity, suddenly took to drinking water, to living on barley bread or millet, and to lying on the ground with a tiger-skin only under him, and thus fell

ill in 1665, the celebrated comet year. An aged, tottering monarch fell violently in love with a girl of thirteen, and, consulting the advertising silent friends of the day, they nearly killed the wicked old gentleman with nervine tonics and electro-curative restorers, which in modern days have been well exposed in the "Revelations of Quackery" by Mr. Courtenay.

Tavernier, the jeweller, who described the Koh-i-nor, tells curious tales, for instance, of Goa, where the hospital patients mostly came out in their coffins after treatment by blood-letting, beef-broth, rice, sweetmeats, and three glasses of cow's urine daily; of the barbarities practised on eunuchs, some terribly mutilated, everything cut off flush with the belly, the bladder and urethra seriously injured; of the Persian climate, free from variola, yet up to the age of twelve conducive to eczema; no grit or gravel, except for the intemperate, and, thanks to the dry air, the cases of secondary syphilis very mild. Colic treated by hog's flesh; dysentery by curdled milk, rice, and rhubarb; and fever involved twelve days' hard tea-drinking, the diaphoresis turning everything yellow, even the walls of the sick-chamber.—*Indian Correspondence of the Medical Press and Circular.*

PROSTITUTION IN BUENOS AYRES.—Buenos Ayres has established a law governing prostitution, which resembles in its general characteristics the laws adopted in other countries,—viz., in requiring an examination of the registered prostitutes, imposing fines on clandestine prostitutes and upon men who cohabit with them, and in the absence of any inspection of the physical condition of men resorting to houses of prostitution.—*Medical Press and Circular.*

SIR CHARLES LOCOCK, who died on the 23d of July last, aged 76, won his high place in rather a peculiar manner. Thoroughly but not liberally educated in his profession, possessing no brilliant reputation in the field of medical literature, his success rested almost solely upon such a union of moral and intellectual attributes as fitted him to shine as a fashionable physician.

KILLING TWO BIRDS WITH ONE STONE.—A clergyman who suffered severely from asthma was one day compelled to open a bottle containing the odoriferous pouches of the skunk, in order to relieve himself, while in the pulpit, of an impending attack. The effect was to drive his congregation out of church in a body. (See Wood's "Natural History," vol. i. p. 377.)

THE Georgia State Board of Health is now fully organized, with Dr. V. H. Taliaferro as secretary.

NOTES AND QUERIES.

OBITUARY.

DR. W. W. HOUSEMAN, aged 22 years, died September 7, 1875, of typhoid fever.

He was a graduate of Jefferson Medical College, and Resident Physician of Blockley Hospital. His young life was full of zeal for the work that had been early marked out for him. His bearing in the competitions of

the class was characterized by a modest fairness, a sympathetic glow for his less-favored companions, and a manly endeavor to remedy his own defects.

Thoroughness, by painstaking labor, was his lever of success; but along with this he had a wonderful love and ability for his calling, which certainly promised much for the profession as well as for himself. This completeness of character was exhibited in all his intercourse by a high moral and social deportment. While it cannot but be regretted that so many bright hopes and promises are so soon withered, yet the example he has left commends itself to his companions and associates.

With a well-trained and disciplined mind he entered upon the study of his profession. By a careful and diligent use of all the advanced means for acquiring knowledge, he won the esteem of all his teachers, and took a high standing in his class. At the close of his college course he entered the hospital with his usual energy.

It was while in the pursuit of these cherished aims and in the path of duty that he was taken with disease, which has cost him his life. But even here there is a bright side, and we can leave him safe in a Christian faith.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At a meeting of the Resident Physicians of the Philadelphia Hospital, held Wednesday, September 8, 1875, the following preamble and resolutions were adopted:

"Whereas, It has pleased God in his wisdom to remove from our midst our friend and fellow-laborer, W. W. Houseman, M.D.; therefore be it—

"Resolved, That, while we bow in humble submission to the will of our Heavenly Father, we deeply lament the untimely death of our late friend and associate, whose manly and amiable qualities have endeared him to us and won for him the affection of all who knew him.

"Resolved, That the Medical Staff of the Philadelphia Hospital has lost in him one well qualified to fill the arduous duties of the post which for so short a time he held.

"Resolved, That we extend our most earnest and heartfelt sympathies to his family in their affliction.

"Resolved, That a copy of these resolutions be presented to the family."

JOSEPH BERENS,	L. H. A. NICKERSON,
A. A. McDONALD,	H. A. SMITH,
S. R. GORGAS,	C. W. DULLES,
S. S. DEASE,	A. W. RANSLEY,
H. W. STELWAGON,	W. H. RUSH,
J. F. EDWARDS,	
Resident Physicians, Philadelphia Hospital.	

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 7, 1875, TO SEPTEMBER 13, 1875, INCLUSIVE.

MILHAU, J. J., SURGEON.—Relieved from duty at Fort Columbus, New York Harbor, and granted leave of absence for six months. S. O. 183, A. G. O., September 11, 1875.

SMITH, A. K., SURGEON.—Relieved from duty in Department of the Missouri, and assigned to duty at Fort Columbus, New York Harbor. S. O. 183, c. s., A. G. O.

HEGER, A., SURGEON.—Relieved from duty in Department of Dakota, and assigned to duty at Willet's Point, New York Harbor. S. O. 182, A. G. O., September 9, 1875.

WEEDS, J. F., SURGEON.—Granted leave of absence for one month, on Surgeon's Certificate of Disability. S. O. 182, Department of the South, September 8, 1875.

BROOKE, JNO., ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 182, c. s., A. G. O.

MONROE, F. LE B., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, to report to the President Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of Dakota, for assignment to duty. S. O. 182, c. s., A. G. O.

KIMBALL, J. P., ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 97, Military Division of the Missouri, September 8, 1875.

BYRNE, C. B., ASSISTANT-SURGEON.—Relieved from duty at Willet's Point, New York Harbor, to report to the President Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of Texas, for assignment to duty.

SATURDAY, SEPTEMBER 25, 1875.

ORIGINAL COMMUNICATIONS.

A CASE OF RETRO-PHARYNGEAL ABSCESS.

BY WILLIAM PEPPER, M.D.,

Physician to the Children's Hospital, etc.

INSTANCES of this dangerous affection are so comparatively rare that a certain amount of interest must attach to every case. The name—retro-pharyngeal abscess—is applied to collections of pus forming in the connective tissue between the mucous membrane of the pharynx and the vertebral column. Such abscesses occasionally occur in cases of caries of the bodies of the cervical vertebræ, the pus being prevented from burrowing up and down along the spinal column by adhesions. In other instances, the abscess follows one of the specific fevers, especially those which, like scarlatina or diphtheria, are attended by inflammation of the fauces and pharynx. It is probable that this sequela is more apt to be developed in children of a scrofulous diathesis, in whom the tendency to suppurative inflammation is so marked. Retro-pharyngeal abscess may, of course, occur at any period of life, but, as will be inferred from the causes which have been mentioned, it is very much more frequently met with during the first decade of life. In the following case the affection was developed during advanced convalescence from a very dangerous attack of naso-pharyngeal diphtheria.

Rose L., æt. 32 months; born of very healthy parents. She was attacked with severe faucial and pharyngeal diphtheria on February 7, 1875, the evening preceding the day on which her elder sister died with an attack of nasal and laryngeal diphtheria. No unfavorable symptoms developed themselves; the membrane disappeared from the sixth to the ninth day, and she was quite well by the end of the second week. The treatment comprised large doses of quinia, chlorate of potassium, and muriated tincture of iron; and locally, the application once a day of dilute tr. ferri chloridi by a brush, and the frequent inhalation of lime-water from a steam-atomizer. During the month after convalescence she continued the use of tr. nucis vomicæ and tr. cinchonæ comp. Some slight enlargement of the post-maxillary glands persisted, but she seemed to be improving satisfactorily for six weeks, and I had not visited her for a week, when, on April 6, she was brought to my office looking poorly, and holding her head constantly far inclined towards the left shoulder. Any attempt to move it caused violent crying; the left sterno-cleido-mastoid and left border of the trapezius were rigidly contracted. There was no increase in the slight swelling of the cervical glands, nor any symptom to attract attention to the fauces, and the attack seemed to be rheumatic in character. Two days later she was again brought to my office, when there could be detected increased enlargement of the post-maxillary glands on the left side, and some fullness about the angle of the jaw. The head was still held strongly flexed towards the left. There was no difficulty in swallowing, but examination of the throat showed a swelling on the posterior wall of the pharynx quite high up on the left side. External applications of compound iodine ointment were directed; a solution of forty grains of nitrate of silver

to the fluidounce was applied to the throat, and syr. ferri iodidi ordered internally with full doses of quinia. For the next four days the symptoms grew more serious. She rapidly lost flesh, and failed in spirits and animation. There was constant fever, with tendency to cold sweat at night. She continued to drink milk and beef-tea freely, from thirst apparently; and deglutition was not difficult. Her breathing was constantly very rapid and labored, with play of the alæ nasi. When she was laid down to sleep her breathing became very noisy and snoring, and rapidly grew more and more labored and imperfect, so that it was necessary to rouse her frequently during the night for fear of fatal embarrassment in breathing. On several occasions, the parents' alarm was so great that they gave repeated doses of syr. ipecac until free vomiting occurred, when partial and temporary relief was obtained. The spray of warm lime-water was also freely thrown into the fauces every three hours by a steam-atomizer, and with evident relief, as the little patient seemed to desire its frequent repetition. During the day the symptoms were much less severe, and the child would walk about, or even play a little. The swelling in the pharynx manifestly increased, and did not seem to extend below the level of the epiglottis. In the upward direction, the finger could detect that it bulged above the level of the roof of the mouth. It occupied the left side of the pharynx, projecting from behind the left posterior half-arch nearly to the median line. The mucous membrane covering the swelling, as well as the surrounding parts, was deeply congested; there was, however, no evidence of any tendency to point. The sense imparted to the finger was one of elasticity without any distinct fluctuation. During these four days the child's strength failed rapidly. The expression grew haggard and anxious, with constant play of the alæ nasi, and labored, noisy breathing. The inspiration was especially difficult, and was attended with marked recession of the base of the thorax and violent action of the superior muscles of respiration. The surface was deathly pale, and at times, especially during the night, was bathed in cold sweat. In addition to the other treatment, which was persisted in, hot flaxseed poultices were kept over the left side of the neck and jaw; milk-punch and beef-tea were freely administered.

On the evening of April 12, as the symptoms grew more and more alarming, without any more decided sign of pointing of the swelling, I plunged a tenotomy-knife into it, and made an incision not more than one-third of an inch long. There was an immediate gush of blood, with a small quantity of pus mixed with it; gentle pressure was exerted on the swelling by the finger, and it was found to be very considerably reduced.

The succeeding night was passed much more easily; the treatment was maintained, and gentle pressure was made morning and evening over the swelling. In addition to this, the throat was thoroughly atomized with lime-water three or four times in the twenty-four hours, with manifest relief. About forty-eight hours after the operation, a more free discharge of pus was obtained by pressure than previously, and thenceforward the diminution in the swelling and in the alarming symptoms was rapid and steady.

The pharyngeal swelling subsided in the course of three or four days; the enlargement of the glands on the left side disappeared rather more slowly. The rigidity of the neck was almost immediately relieved, and in the course of a week, despite some irregular febrile action which required antiperiodic doses of quinia for its arrest, the child was quite well.

It will be noted that in this case the abscess occupied a rather higher position than usual, being seated above the level of the glottis. In conse-

quence of this, the train of symptoms which was present differed in some important respects from the ordinary features of retro-pharyngeal abscess; and, as the recognition of the nature of such cases is very essential, I would direct especial attention to these peculiarities.

The symptoms by which this affection is usually distinguished are, fulness behind one or both angles of the jaw; stiffness of the neck, with retraction of the head; great and increasing difficulty in swallowing; difficulty of breathing, chiefly marked in inspiration, with noisy, snoring sound; and, finally, a prominent swelling at some point of the posterior wall of the pharynx, which may be both seen and felt. In addition, there is irregular, sometimes only slight fever, with great restlessness and general distress.

The diagnosis is always difficult at first, before the development of dyspnoea and dysphagia; and it was doubly so in this case, because there had previously been slight fulness at the left angle of the jaw, and because the position of the head and the contraction of the sterno-mastoid and trapezius simulated closely a rheumatic torticollis. Still, bearing in mind the possibility of such symptoms as rigidity of the neck and retraction or drawing to one side of the head being due to deep-seated inflammation of the retro-pharyngeal tissues, our only mode of avoiding an oversight is to examine the pharynx repeatedly in all such cases.

It is well, also, not to limit the examination to the interior of the mouth, but to search carefully along the course of the larynx for any sign of inflammatory swelling there, since, as was clearly shown in these columns by Parry,* many of the symptoms of retro-pharyngeal abscess may be also produced by abscesses connected with the walls of the larynx.

Difficulty in swallowing usually appears early and soon becomes extreme. It depends both upon the mechanical obstruction caused by the swelling, and upon the paralyzing effect of the inflammation upon the pharyngeal muscles. It is one of the most constant symptoms of retro-pharyngeal abscess, and has been observed in cases of abscess connected with the walls of the larynx. But in the case I have here reported there was no decided difficulty in swallowing at any time. This was undoubtedly due to the fact that the seat of suppuration was very high up, being in part above the level of the soft palate, and also well over to the left side of the pharynx. The fact of the absence of this important symptom is very interesting.

Difficulty of breathing is, as would naturally be expected, a very constant symptom, and deserves particular attention, since its peculiar characters are of much diagnostic importance. The swelling obstructs the pharyngeal and faucial space, and interferes with the entrance of air to the larynx; and in some cases, moreover, the abscess extends so low down that there is, in addition, direct pressure upon the posterior wall of the larynx. There is also more or less secretion of tenacious mucus,

which the child is unable to dislodge, and which adds seriously to the existing dyspnoea. It will be noticed, however, that the difficulty of breathing is, as a rule, limited to the act of inspiration, which is usually prolonged, noisy and snoring, and attended with violent effort; the muscles of the neck contract powerfully; the thorax is strongly elevated, and the base of the chest is markedly retracted. On the other hand, expiration is often quite easy and noiseless. When the child is placed in the recumbent position, it frequently happens, as in the case here reported, that the dyspnoea is greatly increased; and the same result follows any attempt to bend the head forward.

The cause of the marked difference between inspiration and expiration must be sought in the relations of the parts affected. During the powerful inspiratory effort, the larynx is firmly held back by the pressure of the surrounding muscles, and thus is encroached more seriously upon by the swelling which projects from the posterior wall of the pharynx. Fortunately, the seat of the abscess is usually about the level of the glottis, so that this effect is somewhat counterbalanced by the decided downward movement of the larynx in forced inspiration, which tends to remove it from the direct pressure of the tumor. In expiration, on the other hand, the tissues of the neck are relaxed, so that the larynx is able to move quite freely forward, and thus facilitate the exit of air. It is possible, also, that these influences are aided by the different relations of the pharyngeal swelling to the inspiratory current as it converges from the buccal cavity to the narrow glottis, and to the expiratory current as it more gently escapes from the larynx.

I have already alluded to the importance of this character of respiration in aiding the diagnosis of retro-pharyngeal abscess; and I will in this connection refer briefly to the affections with which it is most likely to be confounded.

Acute tonsillitis is met with not rarely in young children, and is attended with a painful swelling below the angle of the lower jaw, difficulty in deglutition, and obstructed breathing. This disease is, however, a primary one, and is much more acute in its onset than retro-pharyngeal abscess usually is; though in some cases of the latter affection the symptoms reach an alarming height in two or three days. The swelling is rather lower down, being over the base of the tonsil just *below* the angle of the jaw, and it is usually more considerable, the swelling which attends retro-pharyngeal abscess being frequently only a fulness *behind* the jaw. Still, the only sure and reliable means of diagnosis is, of course, the direct examination of the fauces, which, as I have already urged, should never be omitted in the examination of the acute affections of young children attended with dyspnoea, dysphagia, or swelling about the throat. This will at a glance reveal the true nature of the case; showing in the one the inflamed and swollen tonsil projecting towards the median line, and in the other, the less easily detected prominence on the posterior wall of the pharynx.

Still more important is it to note clearly the points

* Philada. Med. Times, June 14, 1873, p. 580.

of difference between pseudo-membranous laryngitis (true croup) and the affection we are considering. In both the appearance of the symptoms is rather gradual and insidious; and in both, when fully developed, there is urgent dyspnoea, with great restlessness and general distress. The recession of the base of the chest which is noticed in both of these affections during inspiration is common to all conditions where there is mechanical obstruction to the entrance of air into the larynx or bronchial tubes.

In membranous croup, however, there is no rigidity of the neck, and the head is not retracted or drawn to one side, as in the case here reported. Dysphagia is absent; and the difficulty in breathing, instead of being limited to inspiration as in retro-pharyngeal abscess, attends both inspiration and expiration, owing to the constant mechanical obstruction caused by the layers of false membrane in the larynx. There is also a much greater degree of suppression of the voice. Inspection of the fauces shows no swelling on the posterior wall of the pharynx, but reveals either a healthy state of the parts, or else the familiar lesions of pseudo-membranous angina.

In the rare cases of abscess connected with the cartilages of the larynx, the swelling may encroach seriously upon the calibre of that tube; respiration is accordingly terribly embarrassed, and here too the difficulty is usually limited to inspiration. In the cases reported by Parry, to which I have already referred, the difficulty of inspiration was extreme, and attended with marked recession of the base of the thorax. The head is retracted, and any attempt to bend it forward causes great increase of the dyspnoea. Deglutition may be much impeded, and inspection of the neck shows that the larynx is unusually prominent, and that there is swelling over the thyroid cartilages. Although at first sight such a case might be taken for one of retro-pharyngeal abscess, the diagnosis will be readily made by noting in addition the absence of fulness behind the angle of the jaw and of any prominence on the posterior wall of the pharynx. Dr. Parry describes the breathing in his cases as stridulous as in membranous croup; while in retro-pharyngeal abscess the respiration is rather noisy and stertorous.

I have dwelt at length upon the mode of recognition of this latter affection, because I am sure that its termination would be much more favorable than is usually stated, if a correct diagnosis were made at an early stage and proper treatment instituted.

In those cases where the abscess is connected with caries of the cervical vertebrae, the prognosis is, of course, more unfavorable, owing to the persistence and character of the cause.

So soon as the nature of the disease is recognized, a most careful and constant watch should be kept over the development of the symptoms and the progress of the abscess. Attempts may be made to prevent suppuration by applying, as I did in the case I have here reported, a pretty strong solution of nitrate of silver over the swelling; but it is not likely that our efforts will succeed. I would rather advise that hot poultices or fomentations should be

applied to the neck, to favor early suppuration. Great relief will also be afforded by the occasional use—once in three or four hours—of warm lime-water, thrown by a steam-atomizer into the fauces. This relaxes the parts, and favors the expectoration of the tenacious mucus which often collects there and further impedes respiration. In the present case it was used with manifest advantage. It will also be noted that on several occasions, when the dyspnoea became alarming, temporary relief was secured by producing emesis.

The most essential part of the treatment is the early opening of the abscess. We must not wait for any distinct tendency to point, since, owing to the character of the tissues, there is no such appearance presented in many cases. Whenever, therefore, the symptoms are growing somewhat urgent, a curved bistoury, with its blade guarded to within a half-inch of the point, should be fearlessly introduced into the swelling. No harm can follow from such an incision should it be premature and no pus have yet formed. If the symptoms persist and the swelling increases, it can readily be repeated when thought desirable; whereas it is in the highest degree important that relief should be afforded at the earliest possible moment.

It will be observed that in the present case but little pus escaped at first, but that on the next day, by pressing upon the swelling with the finger, a much larger quantity escaped. This precaution of gently pressing upon the swelling should be observed each day until the swelling has greatly subsided, since, even when there has been quite a free discharge, there is danger of the incision closing and the abscess being reproduced.

During the whole course of the treatment it is, of course, highly important that the strength should be maintained by the administration, so long as swallowing is possible, of quinia, stimulants, and concentrated nourishment. If deglutition is much obstructed, recourse should be had to the use of nutritious enemata, to which a moderate amount of quinia may be added.

1811 SPRUCE STREET.

FUSIFORM ANEURISMS OF ANTERIOR AND POSTERIOR TIBIAL ARTERIES—DIGITAL COMPRESSION—CURE IN THIRTY-SIX HOURS.

BY DE FOREST WILLARD, M.D.,

Surgeon to Out-Patient Department, Presbyterian Hospital.

THE following case is deemed worthy of record chiefly on account of the shape of the aneurisms, which rendered the formation of a clot much more difficult than in the sacculated form, where the force of the heart-beat is driven less directly upon the forming coagulum. In the present instance it was necessary to use great care at each change of the compressing fingers, since any relaxation of the calibre of the vessel above, was sure to send the current whirling through every portion of the tumor, displacing all fragments of hitherto stagnant blood.

The case also adds to the rapidly accumulating evidence of the superiority of compression over the

ligature in a large proportion of cases. The ready cure of unfavorable cases, and its adaptability to aneurisms in which, at first sight, the treatment might seem to be inapplicable (vide Prof. Agnew's cure of aneurism of external iliac, *Philada. Med. Times*, 1875), both tend to render it most justly a favorite method.

S. T., æt. 66, shoemaker, was first seen on July 15, in consultation with Dr. M. O'Hara, the attending physician. Had been under Dr. O'Hara's care only a few weeks for an albuminuria of long standing, accompanied by slight dropsy. When first seen, was passing a moderate amount of pale urine, sp. gr. 1.012, which was one-quarter albumen, and contained numerous fatty and granular casts. Under treatment with mist. Basham, milk, etc., the albumen had decreased to one-twelfth, and the dropsy had entirely disappeared.

In June he commenced to complain of pains, resembling cramps, in both legs below the knees, which pains were not definitely located, but were of increased severity at night. Embrocations and friction failed to give relief. About July 1 he took a long walk, which fatigued him, but he states that he had no inconvenience from it until several days afterwards, and that he never experienced the sensation of anything "giving way." By the 4th, however, the pains became so severe as to compel him to keep his bed, save at night, when the torture necessitated his rising at least a dozen times to seek comfort for the moment by change of posture. He described his pain as almost unendurable, until electricity (interrupted current) was tried, when complete relief was experienced in the right leg, but the left continued in the same condition as before.

Upon the 10th, pulsation of the calf of the limb was noticed for the first time, and, upon closer examination, the presence of an aneurism was easily detected.

On the 15th, at the time of my first visit, the pulsation was most marked, the whole calf of the leg rising at each heart-stroke, the anterior muscles also vibrating, and the head of the fibula being distinctly driven outward at each beat. Notes taken at that time are as follows: The hand placed upon any portion of the leg from the insertion of the soleus upon the tendo Achillis, to the knee, feels most decidedly the characteristic thrill, while the fibula is forcibly thrust against the finger. There is no well-defined and limited tumor, but a general enlargement of the entire leg. The pulsation is strongest over the lines of the two main arteries, and the ear along their course plainly detects a loud bruit. There is no undue pulsation of the popliteal, nor do the thrill and bruit extend to that artery. The dilatation evidently commences just at the point where the bifurcation occurs, *i.e.*, at the lower border of the popliteus muscle, where the anterior tibial runs between the two heads of the tibialis posticus to pierce the interosseous membrane and reach the front of the leg. Both arteries are largely dilated, but apparently taper towards the ankle, where the normal calibre is resumed. Pressure upon either femoral or popliteal entirely arrests all pulsation, thrill, and bruit, and also relieves the pain. The swelling of the foot is but slight, yet the pressure is not only causing intense pain, but has already produced tingling and loss of power in the toes, especially those supplied by the musculo-cutaneous branch of the anterior tibial.

Strong flexion of the limb does not entirely arrest pulsation, and is extremely painful. There is no cardiac complication, but all the arteries are atheromatous, and, with the extensive renal disease, ligation would be at best dangerous.

Compression, therefore, was strongly advised, and was commenced upon the 17th, Prof. Agnew having

also been called and pronouncing decidedly in its favor.

17th. 12.15 P.M.—Commenced pressure upon femoral in Scarpa's triangle; Dr. O'Hara and myself having organized a corps of reliable co-workers. Pulse 96. Condition excellent.

[NOTE.—As many surgeons may be deterred from commencing digital compression from want of assistance, I would state that I am convinced, from some fifteen cases with which I have been connected, that it could be safely undertaken by four strong gentlemen, provided they had no other labors to perform. Six would be better (especially if the artery lay deeply covered by adipose and connective tissue), one-half sleeping while the others took their respective turns at holding the artery. After practice, one can, by changing from thumb to fingers, etc., keep up reliable pressure for from thirty to fifty minutes; but twenty is, perhaps, the most economical so far as permanency is concerned.]

17th. 4 P.M.—Left leg dry; right, moist; no perceptible difference in temperature. Pulse 84.

6 P.M.—Slight oedema of entire limb. Tissues over femoral "crackle" on pressure. Still dryer than right, and apparently warmer. Veins distended.

9 P.M.—Foot slightly cooler.

11.30 P.M.—Less oedema. Slight excoriation at seat of pressure; yet is more comfortable than before treatment was commenced, as the severe pain in the leg has been entirely relieved. Eats well.

18th. 12 A.M.—Beginning to be a little restless.

12.30 A.M.—Administered one-fourth grain morphia, hypodermically.

2 A.M.—Pulse 82. Dozes and sleeps; not suffering.

7 A.M.—Pulse 78. Foot quite cool. Leg and thigh greatly swollen. Tissues in Scarpa's triangle exceedingly sensitive and doughy; blistered at one point. Suffers much at change of fingers. Capillary circulation in foot slow. Thrill barely perceptible.

Pulse 82. Ate good breakfast, and is in good spirits; read paper. Now apply pressure at apex of triangle and in canal.

8 A.M.—No thrill.

9 A.M.—One-fourth grain morphia, hypodermically.

12 M.—Tissues greatly improved, and oedema lessened, as all pressure has been made low down in adductor canal for five hours. Has been dozing.

4 P.M.—Pulsation perceptible in articular branches.

8 P.M.—No pain. Temperature of limb nearly as other. Comfortable. Pulse 84.

19th. 12 A.M.—Pulse 94. Pulsation in tumor very faint; in fact, very doubtful if it exists at all. Hardening. Great pain over femoral, but condition and spirits good. Eats well, and dozes. One-fourth grain morphia, hypodermically. Good capillary circulation in foot and leg; oedema moderate.

12 P.M.—No pulsation in tumor.

3 A.M.—Pulse 78. Sleeping.

4 A.M.—Considerable pain, as tissues, even low down in canal, are becoming sore. Dilatation of articular branches at knee so great that slight pressure was made upon femoral above profunda, to limit but not control the circulation. One-fourth grain of morphia, hypodermically. Passes water often, and with difficulty.

5 A.M.—Dozing.

8 A.M.—Ate good breakfast. Cheerful. Not much pain; oedema slight. Temperature of limb good.

12.15 P.M.—Aneurism pronounced cured, but cautionary pressure to be continued until evening. No signs of pulsation below popliteal, although that artery beats quite strongly. No perceptible pulsation at foot in either anterior or posterior tibial; slight in articular branches at knee.

4 P.M.—Oedema of leg more marked; surface colder;

capillary circulation, however, good. One-fourth grain morphia, hypodermically.

7 P.M.—Ceased compression. Placed limb in flexed position. No pulsation to be felt in any portion of leg below knee, nor over any artery there. Gave one-eighth grain morphia, hypodermically.

Summoned at 10 P.M. Reaction, together with morphia, had made him restless and delirious; tossing about; partly due to full bladder; drew three pints; gave fifteen grains chloral; slept soundly and quietly until morning.

20th. 10 A.M.—No pain; no pulsation. Pulse 96. During the day seized with diarrhoea, with fever and hot skin.

At 10 P.M., pulse 106; skin hot; tongue dry and brown; no chill; bowels loose, dark, and offensive; cannot pass urine—drawn with catheter. Gave two grains quinine and ten gtt. ol. terebinth. every three hours; paregoric after stools. Stopped Basham's.

21st.—Slept well. Tongue more moist. Pulse 96. Feels brighter. Diarrhoea ceased. No pulsation in tumor.

In evening, great pain from accumulation of urine; much suffering; passes a little himself, but not relieved; drawn; thick, turbid.

22d.—Slept well without medicine. Urine giving great suffering; drawn with catheter; thick with mucus and urates. Tongue moist. General condition good. Sat up in bed for the first time.

For the next few days Dr. O'Hara reports that he had a sharp attack of cystitis, which required the use of the catheter several times a day, but in a week or ten days this disappeared under appropriate treatment, and although the albumen in his urine had greatly increased during its continuance, yet it subsequently subsided, and by August 10 was scarcely perceptible.

He went about on crutches at the end of the third week, and in six was permitted to walk about; suffering no pain in the limb, and with no inconvenience, save the swelling and debility occasioned by the chronic Bright's disease.

September 15.—No evidence of any return of aneurism, but the kidney-disease is progressing, and renders him feeble and debilitated, although the œdema is but trifling. The aneurismal limb is weak, and use frequently gives pain, but the old seat of trouble remains the same as two months ago. No pulsation is perceptible over either the anterior or posterior tibials until they have almost reached the angle, at which point the pulse returned within three or four days after the cure. The popliteal beats as usual, but from the point of bifurcation to the ankle the occlusion seems perfect.

It will be noticed that all thrill ceased during the treatment at the end of twenty hours, and that pulsation stopped at thirty-six, but that pressure was continued until the end of fifty-five hours in order to prevent any displacement of the coagulum. The severe cramps in the legs mentioned above, which antedated the aneurism, were undoubtedly due to the debility, indigestion, etc., consequent upon the condition of the kidneys.

During treatment by digital compression it is very important that great care be exercised during the changing of fingers that the calibre be not relaxed, since the full force of the heart-beat would almost certainly disturb the forming coagulum. It is also advisable that a second person sit with his hand upon the tumor, to give notice of any relaxation upon the part of the holder, since continuous, equable muscular contraction is almost an impossibility, the pressure, however hard at first, gradually becoming insensibly less and less, until it not un-

frequently happens that the calibre is not more than one-half occluded, while the holder innocently supposes that he is pressing with the same amount of force as at the beginning, owing to benumbed sensation.

The following gentlemen kindly assisted in the cure of this case: Drs. Curtin, Buck, Treacy, Brunet, Evans, Gleason, Caldwell, Kerr, Skilling, Witmer, and Parks, and Messrs. Klapp, Walsh, G. C. Smith, Almeida, and Murray.

113 SOUTH SIXTEENTH STREET.

REMARKABLE PERSISTENCE OF CARDIAC ACTION AFTER CESSATION OF RESPIRATION.

BY R. STEWART, M.D.

THE verdict recently rendered by a jury at Dover, Delaware, that a child had an independent existence although it did not breathe, leads me to publish the following remarkable case. Shortly after its occurrence, I gave a detailed account of it before the Sydenham Medical Coterie of this city, and since then it has been referred to by Dr. Seyfert, in his article on "Living Issue," in the *Medical Times* of July 3, No. 192, vol. v.

On July 4, 1872, about five o'clock P.M., I was called to visit a gentleman nearly 72 years of age, who prior to that time had enjoyed ordinarily good health. During the forenoon he had walked to the Park and back, a distance of some ten or twelve squares, and when he reached home he complained of great fatigue, heat, and some pain in the head. Of his own accord he took the contents of a bottle of citrate of magnesia. After prescribing for him, I left; but before eight o'clock I was again summoned, and upon reaching the house, a few minutes afterwards, I was informed that the old gentleman had just expired. He had arisen to make use of the commode, and was found upon the floor, being unable to reach his bed again. After being placed in bed there was an involuntary action of his bowels, after which he gradually became insensible, and ceased breathing just as I entered the room. I found the jaw fallen, eyes fixed, body cool, and the head hot. After looking at him for a moment, I said, "Yes, he is dead." On applying my ear to the chest I distinctly heard the heart beating slowly, at the rate of about twenty-seven to the minute. I at once attempted artificial respiration by alternately raising the arms and pressing the sides of the chest together, and I blew air and ammonia-vapor into his lungs. I was surprised to find that under this treatment the heart-beats became more frequent and forcible, while a general rigidity was becoming very apparent. After a short time had elapsed, I placed a small mirror over his mouth, and, although I held it there for some time, making careful and repeated examinations of its surface, I could find nothing to indicate that he breathed.

At this time I was called away to another patient, and did not return until ten o'clock, when, upon making another examination of the chest, I readily detected the pulsations of the heart. By making

pressure upon the thoracic walls, squeezing the ribs together, and then allowing them to relax, the pulsations were again increased in rapidity and force. I then inflated the lungs by closing the nostrils and blowing into the mouth, raising the arms above the head, and expelling the air by pressure on the chest, etc. By a constant repetition of these efforts I at last increased the force of the heart to such an extent that a radial pulse became perceptible. To this fact I called the attention of those who were present. The head was still warm, but the body had grown colder and more rigid, and on this account it was becoming more difficult for me to continue my exertions. I went away at 11.45, and returning between one and two o'clock A.M., I found the heart still slowly beating. I endeavored to press the ribs together, but the rigidity was so great that I found it an exceedingly difficult task. I struck the chest quite forcibly over the region of the heart, and indented or pressed the ribs quickly downwards, which again increased the heart's action, but less than it did before. The jaws were now fixed, tongue stiff, and the arms stiffly extended by his sides. Getting upon the bed, I found that by placing my hands under his head I could raise the entire body without any signs of flexion, and I repeated this act several times. By thumping and pressing upon the chest, I kept the heart in quite regular motion until nearly four o'clock, when I went away.

On returning, between five and six o'clock A.M., I could hear a slight throb, but very slow, and could not increase it. I then left, and when I returned a little after eight o'clock, there were signs of decomposition, by appearance, odor, and lessening rigidity. He was evidently dead *now*; but was he dead before?

After twelve o'clock the heart was made to beat more rapidly by external manipulation only, and not by any vapor forced into the lungs. In fact, from the first, pressure upon the chest at once increased the heart's action. It may be suggested that I was observing the rhythmical movements of the muscles of the chest; but such movements could scarcely be regularly and constantly increased without a *visible* motion, and yet give an audible throb like that of the heart; and much less could such an action produce a *radial pulse*. Furthermore, if muscular excitation is admitted as being probable, why should we exclude the heart, which is one of the most irritable muscles of the body? If he was alive, then cadaveric rigidity may take place before death. If he was not alive, then this is a remarkable instance of retained irritability of the heart after death. Is not respiration the fundamental requisite of independent life? Is it not the first indication of independent existence? If this man breathed, he was alive; if not, we declare him dead, whether the heart was irritated into action or not.

A very charitable explanation may be given by assuming that I was mistaken in my observations. To this I reply that I know I was not. This was not a momentary condition, but one lasting long enough for a calm and most careful examination. If a similar case is not on record, it does not follow that none such have occurred, as only circumstances lead to the publication of this. But it may be that

some reader of this article may know of one like it, and, if so, this may lead to *its* publication. The statements being true, the question I would have answered is, *Was he alive?*

1838 GREEN STREET.

FAILURE OF BROMIDE OF IRON IN CHOREA.

BY CHARLES K. MILLS, M.D.,

Philadelphia,

Chief of Clinic for Nervous Diseases, Hospital of the University of Pennsylvania.

CHOREA, like the correlated disorder, rheumatism, has suffered many things of many remedies. It is certainly a disease which can be favorably influenced by different drugs and by various modes of treatment. Bromide of iron has lately been strongly recommended for it by Professor J. M. Da Costa. In a lecture on chorea, reported by Dr. F. Woodbury in the *Medical and Surgical Reporter* for January 30, 1875, referring to bromide of iron, Prof. Da Costa says, "Having now used it for three or four years, my experience from the treatment of a large number of cases giving abundant opportunity to witness its good effects induces me to like it better than any other one article in the treatment of chorea."

Since reading Professor Da Costa's remarks, I have tested the remedy in twelve cases of chorea, chiefly in the clinical service of Professor H. C. Wood, at the Hospital of the University of Pennsylvania, and have been entirely disappointed in the preparation. In no case was any permanent benefit derived from its use. In two instances slight apparent improvement was noted, but it was only transient in character. Much better results can be obtained from other salts of iron, and from other remedies, such as arsenic, cicicifuga, and the bromide of potassium.

It was usually given in plain syrup and water, commencing with five grains three times daily, as recommended, and rapidly increasing the dose to twenty. The treatment was continued from two to four weeks. Twenty grains very generally caused vomiting. It seems to be a remedy which quickly irritates the intestinal tract. In the case employed by Professor Da Costa to illustrate his lecture, this fact was noticed. The child under treatment became affected with a troublesome diarrhœa, requiring the substitution of bismuth for the iron, and several attempts to return to the bromide were foiled by this irritability of the digestive tract, which refused to tolerate the drug. Fowler's solution was finally given in its place.

Most of the cases in which the bromide of iron failed were afterwards cured either by arsenic, arsenic and iron, or cicicifuga, assisted by hygienic measures. In local chorea or clonic muscular spasm, for which this remedy is advised after the failure of other methods of treatment, I have not found it of any value. Very rarely indeed will any drug improve these local affections.

Dr. J. B. Rudderow informs me that he has used

the preparation under consideration without success in several cases of chorea.

In addition to the twelve cases of chorea referred to, I have also unsuccessfully employed the bromide in a few cases of hysteria and epilepsy. Theoretically, the combination of bromide and iron would appear to be a good one for the treatment of a neurosis like chorea, and it is well known that any of the numerous remedies which have been employed successfully in this disease may sometimes prove futile; but the failure of the bromide of iron has been so marked in my experience that I have thought it worth while briefly to call attention to the fact.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF HARRISON ALLEN, M.D.

Reported by Dr. JOSEPH BERENS, Resident Physician.

MULTIPLE FISTULÆ IN ANO—TREATMENT BY ELASTIC LIGATURE—CURE IN FOUR WEEKS.

CASE I.—P. W., æt. 39; Ireland; good family history. According to his own account of himself, he first had pain in the anal region two or three years ago; two or three months subsequent to this an abscess formed to the left of the anus, and in close proximity to it. This was opened by a physician, and there soon became established a fistula, which persisted for seven months, when it closed spontaneously. The closure of this was almost immediately followed by a second abscess, a little to the left of the coccyx, preceding another fistula, which still persists. These fistulæ were followed at irregular intervals by others which developed in succession, one a little posterior to the great trochanter of the left thigh, one in the perineum one inch anterior to the anus, a third on the left ischiatic tuberosity. These all gave vent to occasional discharges of feculent matter and wind, the latter often producing emphysema of the neighboring tissue.

Upon examination, the fistulæ were found to be of unusually large size, with orifices that did not pout, and occupying the positions enumerated above. The contiguous tissue was purplish in hue, very brawny, and at points presenting unequivocal evidence of emphysematous infiltration. Probing established communication of all the tracks with one another, and, after patient search, the instrument passed from the opening over the ischium into the rectum at a point just below the internal sphincter. A rubber ligature was attached to the probe, drawn through and out at the anus, secured by a bow-knot, and permitted to remain. Laxatives for the bowels were ordered, the ligature to be tightened as required. Two weeks after the operation an abscess appeared over the right ischium, which, when opened, discharged a large quantity of brown flocculent pus.

Upon the sixteenth day, aided in small degree by the knife, the ligature came away, leaving a healthy granulating wound. By the end of the third week the condition of the patient was rapidly improving; the abscess last mentioned had completely healed, the wound left by the ligature uniting rapidly, but the fistulæ still patulous,—a thin layer of tissue between the fistula and the rectum remaining intact. This was divided by a bistoury.

The end of the fourth week witnessed the termination of the case and the complete cure of the patient.

PERINEAL ABSCESS—URETHROTOMY.

Case II.—W. Y.; 43; Pennsylvania; entered the house suffering with a large circumscribed swelling in the perineum, which was somewhat red and warm to the touch, but yielded no sense of fluctuation.

The patient states that ten years ago he had a gonorrhœa, which was followed in the course of a year by a stricture. He placed himself under the care of a physician, and, with the occasional passage of a sound, suffered little inconvenience until two months ago, when, after a debauch, his stricture suddenly became very much worse. About two weeks ago he began to suffer pain, which was accompanied by a feeling of fullness and weight in the perineum. These symptoms were particularly severe in walking, subsiding almost entirely in the recumbent posture.

A whalebone filiform bougie was passed with no little difficulty, and over this a No. 14 (French) grooved catheter. The tumor was now laid open by an incision in the median line, carried from the scrotal border to within a half-inch of the anus; this gave vent to a quantity of laudable pus, after the evacuation of which the point of the knife was carried down through the urethral wall until it entered the groove in the staff, after which the urethra was laid open to the extent of an inch. This cut relieved the stricture, a large sound passing in readily.

First day after operation.—Patient doing well, passing water freely by the urethra.

Second day.—Water passing through the perineal aperture; patient very feverish.

Sixth day.—A No. 10 (French) soft catheter was the only instrument that could be introduced, and that with such difficulty that it was permitted to remain in the passage.

Eighth day.—The instrument removed, and a No. 24, which passed in easily, substituted.

Tenth day.—The instrument was removed, and, as there existed a tendency to irritability and spasm of the canal, no further dilatation was attempted at the time.

Thirteenth day.—Instruments have been introduced daily until, this morning, No. 27 was attained. The condition of the patient has been steadily improving; the wound in the perineum is closed, though not completely healed. The urine, which has been passing by the perineal opening in daily decreasing quantity, now comes entirely by the natural channel, and in an excellent stream.

Sixteenth day.—Patient well, with a urethra that readily admits a No. 27 (French) instrument.

STRICTURE—PERINEAL FISTULA.

Case III.—P. H.; 70; Ireland; admitted to the house suffering from an abscess in the perineum, which had ruptured spontaneously the day before, and was then discharging pus freely. In urinating he passed his water by the perineal orifice, none escaping by the penis.

He stated that he first had difficulty in urinating three years ago, since which time he has grown progressively worse. As the patient was reduced by exposure and starvation to the last extreme, and appeared to have a very tight stricture, nothing was done further than laying open the abscess by a free incision and placing him under favorable hygienic conditions. In a few days the patient's strength had improved so much that it was decided to make an attempt to treat his stricture. Patient search of half an hour, however, failed to secure the introduction of even a filiform bougie, and the attempt was desisted from. A week after, a small, probe-pointed sound was passed into the bladder, followed by larger ones until No. 8 (French) was reached. The seat of the stricture appeared to be just anterior to the bulbous portion of the urethra. Subsequently in-

struments were cautiously introduced every second day, gradually dilating the passage until it admitted a No. 20 (French) sound. Any increase in size beyond this producing profound constitutional disturbances, it was thought best to rest here, and merely prevent any retrogression. Meanwhile, the urine had begun to pass by the penis, and the abscess in the perineum to heal. In the course of a month this improvement advanced to complete recovery as to the abscess and resulting fistula, and a decided amelioration in the general condition of the patient, both as to his stricture and general condition.

GORRORRHEAL RHEUMATISM.

Case IV.—Wm. McF.; 49; Ireland; entered the house three months ago, suffering from a gonorrhœa of two weeks' standing, which at the time of his admission was particularly severe. The day following, an attack of rheumatism supervened, beginning in the right ankle and gradually extending till many of the points of the body were affected, and, with exacerbations and remissions, has persisted ever since. The gonorrhœa, also, has been subject to fluctuations in severity, and seems to have borne a relative proportion to the rheumatism. Thus, on July 4 the gonorrhœa, which had been manifesting itself by a profuse discharge, suddenly disappeared almost completely, following which there was an as sudden exaggeration of the rheumatic symptoms. On the morning of the 11th the patient remarked, "The rheumatism is getting well; but, doctor, the clap is running awful." In truth, the rheumatism had nearly subsided, while there was a profuse purulent discharge from the urethra, with a red and inflamed meatus. On the 31st the patient was again down with the rheumatism, synchronously with a marked subsidence of the gonorrhœa. A turpentine vapor-bath was ordered, to be followed by a blanket pack. In the afternoon there was an evident improvement in the rheumatism, while the gonorrhœa had resumed nearly its former severity. Until about the middle of August, when all the symptoms began to subside, there existed a marked and unmistakable correlation between the two diseases from which the patient suffered; the severity of the one being generally in the inverse ratio to that of the other, neither ever completely disappearing, but each in turn being more or less pronounced or in abeyance.

AMPUTATION OF THE LEG.

Case V.—John McG.; 22; Delaware; temperate; was run over by the cars on August 16, at 9.30 P.M. He was brought to the house in the ambulance two hours later. On admission, he was suffering from moderately developed shock, and had injuries which comprised a crush of the right ankle-joint, which had produced a compound comminuted fracture, involving the lower end of the tibia, and the tarsal bones, with large openings opposite each malleolus, through which protruded the fragments; in addition, there were two incised scalp-wounds, one of them four inches in length, crescentic in shape, and attended with considerable separation of the scalp from the skull.

Amputation was decided upon, and the operation begun immediately. Ether was administered, Esmarch's bandage applied, antero-posterior semicircular skin-flaps were made, and the two bones divided at the junction of the lowest and third quarter of the leg. But little hemorrhage ensued. The vessels were secured by silk ligatures, after which heavy silk sutures were introduced through the flaps and the wound left open for some fifteen or twenty minutes, when it became glazed. The flaps were then adjusted, secured by the sutures, which were tied in bow-knots and supported by adhesive strips, so arranged as to prevent any dropping down of the anterior flap upon the end of the

tibia, the end of which had been carefully rounded off. A dry oakum dressing was then applied. The scalp-wounds were apposed by interrupted silver sutures, and the patient put to bed between blankets and surrounded by cans of hot water.

The leg was placed upon a pillow, adapted to give further support to the flaps and so prevent pressure. An ounce of whisky and a quarter of a grain of morphia were administered.

For the first few days succeeding the operation, the patient had a slow pulse, with stupor and other indications of injury to the nervous centres. At the end of this time, however, there was very marked improvement in his general condition.

Fifth day.—As there had been little or no discharge, the adhesive strips were removed for the first time to-day. The stump was found looking admirable, with almost complete healing by first intention.

Ninth day.—Several of the ligatures came away. There is, however, well-defined heat and swelling over the point of the tibia. Dr. Allen ordered the suspicious point painted night and morning with tincture of iodine, and, as a further precautionary measure, additional support given to the flaps by placing upon the posterior aspect of the limb, far up near the popliteal space, the initial end of a piece of adhesive plaster four inches wide by two feet long. This strip was designed to so support the posterior flap as to relieve the dragging of the anterior flap upon the spine of the tibia. The free end of the strip was pulled strongly upward over the face of the stump, and fixed to the transverse wooden support for the bedclothes. This simple contrivance *swung the entire limb by the posterior flap a few inches above the level of the mattress*. Its effect was to *wrinkle* the anterior flap, at once relieving all pressure. The redness over the tibial spine disappeared, and a threatened danger of slough was averted. To relieve jactitation, two lateral strips were applied from the knees downward, and a weight applied to them as in the treatment of fracture.

The scalp-wounds healed by first intention.

Thirteenth day.—All the sutures and ligatures but one have been removed at intervals since the last note. The device for preventing the sloughing of the flap over the tibia has been entirely successful.

Sixteenth day.—By daily twisting of a rather resistant ligature, and the fastening it so as to retain the twist, it has been gradually severed from its attachments, and to-day came away without difficulty.

Seventeenth day.—Patient well.

TRANSLATIONS.

THE CONJUNCTION OF CHLOROSIS WITH APLASIA OF THE FEMALE GENITAL ORGANS (E. Fraenkel: *Archiv für Gyn.*, vii.; from *Schmidt's Jahrbücher*).—Fraenkel reports two cases, as follows. 1. A servant-girl, aged 26, who was of powerful frame, had never menstruated, and presented some symptoms of chlorosis. Her heart was of normal size, and no râles could be detected by auscultation, but a microscopic examination of the blood showed a marked diminution of the number of red blood-corpuscles. Her breasts were infantile in character, and the pelvis diminished in all its diameters and of masculine form. The labia majora were entirely wanting, the nymphæ but slightly developed, while, owing to a want of development, the hymen was wanting. The uterus was very small, and its walls quite thin, and the presence of ovaries could not be distinctly ascertained.

2. A girl of 20 years of age, who, in childhood, had scar-

latina and cholera. The first menstruation was profuse, and occurred in her seventeenth year, and the performance of this function was attended by fainting, dyspnoea, and palpitation of the heart. The face was pale, the extremities chilly, and there was pneumonia of the apices. The heart was small, its impulse weak, while the pulse was thin and thready. The genitals resembled those of a girl of seven or eight years, the mons being without hair, the uterus small and infantile in character, and the breasts small.

Fraenkel concludes that chlorosis is often combined with defective development of the genital organs, but not always with defective development of the heart and aorta. Sexual aplasia may be the first cause of chlorosis, but chlorosis, when the heart is not of small size, is permanently curable. Menorrhagic chlorosis occurs as well when the sexual apparatus is defective as when it is excessive in its development. W. A.

ON THE ASSIMILATION OF STARCHY FOOD BY INFANTS (Dr. J. Korowin: *Schmidt's Jahrbücher*; from *Jahrb. für Kinderheilk.*, viii. 4).—This question is not only of great physiological interest, but is also of the highest practical importance, since all the substitutes for mothers' milk which have as yet been recommended contain starch in larger or smaller amount. Dr. Korowin had great trouble even with very young children in collecting a sufficient quantity of saliva for his purpose by introducing a sponge in the mouth after it had been carefully cleansed. He found that towards the end of the second month the saliva increased most markedly in quantity, and that this increase continued during the following months. The reaction of the fluids of the mouth when this cavity had not been scrupulously cleaned was strongly acid, and, after it had been carefully washed, slightly acid or neutral, but rarely weakly alkaline. The first experiments were made with the saliva of children varying in age from half an hour to nine days, and revealed almost invariably a distinct trace of sugar. Experiments with children of rather more advanced age showed that the fermentative power of the saliva increased with the age of the child. The greatest quantity of sugar was not found until fermentation had been going on for about two hours.

Experiments with the contents of parotid glands which had been excised also gave evidences of a sugar-making power. Similar experiments with the secretion of the pancreas from children who had died during the first three weeks gave negative results, and the power of inducing fermentation became gradually noticeable at a later period, but remained feeble up to the end of the first year. W. A.

INTESTINAL OBSTRUCTION SUCCESSFULLY TREATED BY THE INJECTION OF SODA-WATER INTO THE LARGE INTESTINE (Guyon: *Centralblatt für Chirurgie*, No. 34, 1875; from *Journal de Méd. et de Chir. prat.*, 1875).—The patient, a man aged 62 years, had an inguinal hernia which had been reduced after symptoms of incarceration had made their appearance. Some hours later, vomiting set in, which soon became fecal in character, and was accompanied by symptoms of collapse. An œsophageal catheter was introduced into the rectum to an extent of forty centimetres, and through this the contents of two siphons (the contents of the first in great part escaping) injected into the intestine. Colic of a marked character soon came on, which was followed by the evacuation of stinking fluid matter, and this, in turn, by hard fecal masses; and after the expiration of two hours the patient was out of danger.

Béhier in one and Bouchut in ten cases of intestinal obstruction from impacted masses of feces, employed the same treatment with good success. In all the cases the abdomen swelled on the introduction of the gas,

producing colic of intense character, which was soon followed by evacuation of the bowel and consequent relief. W. A.

ETIOLOGY OF SCORBUS (Felix: *Centralblatt für Chirurgie*, No. 34, 1875; from *Gaz. Méd.*, 1875).—In view of the noticeable fact that scorbutus is becoming of less frequent occurrence in Western Europe, while in the east, and especially in Russia and Roumania, it has every year new victims, Prof. Felix of Bucharest turned his attention to the subject, and in 1871 pointed out the relation of the increase of the affection with the diminution of fat in the food allowed during the protracted and strict fasts of the Greek Church. The faithful among the Greek Christians nourish themselves during their periods of fasting exclusively with vegetables and oils of vegetable origin. These oils, however, on account of their high price, are not eaten by the poorer classes, and but rarely by soldiers and the inhabitants of prisons, and it is among these very classes of the population that scurvy breaks out a short time before or after the great religious festivals. In accordance with this theory he prescribes, instead of the usual diet for such patients, one rich in fats, and aids its effects by the administration of cod-liver oil. W. A.

EXTIRPATION OF A MYOMA OF THE BLADDER AFTER THE LATERAL AND HIGH OPERATION FOR LITHOTOMY (C. Gussenbauer: *Archiv für Klinische Chirurgie*, 1875; from *Centralblatt für Chirurgie*, No. 28, 1875).—In a boy aged 10 years, Billroth, after repeated and careful examinations, diagnosed a tumor of the bladder of the size of a man's fist, which had been developed during the previous ten months. In order to remove the tumor the usual lateral incision into the bladder was made, and it was found that it lay on the posterior wall of the bladder. The sectio alta was then made, the recti muscles cut obliquely at their insertion, and the wound in the bladder enlarged in the same direction. The attachments of the tumor were torn off with the fingers, and, the bladder having been moderately inverted, the pedicle of the tumor, which was found to originate in the muscular tissue of the vesical walls, was excised. A drainage-tube was placed in the wound of the bladder, and recovery took place in about four weeks. A microscopic examination of the tumor revealed the characteristics of a myoma. W. A.

PROLAPSUS OF THE RECTUM, AND ITS TREATMENT BY THE DOUCHE ON THE ANUS AND PERINEUM (De Saint-Germain: *Centralblatt für Chirurgie*, No. 34, 1875; from *Journal de Méd. et de Chir. prat.*, 1875).—In cases of prolapsus of the rectal mucous membrane in children, in which all other means, even the actual cautery, had been used, a cure was effected by reducing the protruded portion and allowing a strong stream of water to play upon the anus and perineum. The douche was repeated daily. The duration of treatment in the gravest cases was fifty-eight days, and relapses did not occur.

In the case of an adult who suffered from prolapsus recti with hemorrhoids, forty-eight sittings sufficed for a cure. W. A.

A RARE CASE OF MYOMA OF THE UTERUS (P. Sturm: *Centralblatt für Chirurgie*, No. 34, 1875; from *Archiv der Heilk.*, 1875).—The patient was a woman aged 49 years, and the tumor a cystic myoma of colossal dimensions, which was supposed to be ovarian in its character, and an operation for its removal was begun. The operation was, however, suspended, and at the post-mortem examination, which was made soon afterwards, a large myoma was found, which originated at the fundus of the uterus and grew up between the two layers of the mesentery of the small intestine. W. A.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, SEPTEMBER 25, 1875.

PUBLISHERS' NOTICE.

THE present number concludes the fifth volume of the PHILADELPHIA MEDICAL TIMES. With the publication of the next number, beginning the sixth yearly volume, the issue of the TIMES will be made bi-weekly, being published every other Saturday. This change is made with a double purpose: first, to secure a reduction in the price of the journal (to \$4 per annum), a change which seems expedient in view of the financial condition of the country; secondly, to enable the editors to give more time to its editorial management than has hitherto been possible, on account of the frequency of the issue. The editors are confident that, as a bi-weekly, the subscribers, while receiving their journal with sufficient frequency to keep themselves *au courant* with medical progress in the world, will find the original department filled with material which, in practical interest, will be above the average of that which has hitherto appeared in its pages.

During the five years of its existence the TIMES has won at home and abroad a high reputation,—flattering alike to contributors and to editors,—to maintain and enhance which no efforts will be spared. The publishers desire to express their appreciation of the support that has been extended to their journal, and trust that its merits will secure to it a continuance of the same.

The form of the TIMES will be changed slightly, and each number will embrace twenty-four pages (instead of sixteen as hitherto), enclosed in a neat cover.

CORRESPONDENCE.

Boston, September 11, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The meetings of the American Pharmaceutical Association, the twenty-third annual session of which has just been held in this city, possess a twofold interest, for they are of practical value to the druggist and manufacturer of chemicals, at the same time that they suggest to the physician refinements and improvements in the preparation of medicines that may be a guide to him in prescribing.

As the objects of this Association may not be generally known, I may state that its aims are to unite the educated and reputable pharmacists and druggists of the United States in the following objects: To improve and regulate the drug market, by preventing the importation of inferior, adulterated, or deteriorated drugs, and by detecting and exposing home adulterations; to encourage proper relations between druggists, pharmacists, physicians, and the people at large, which shall promote the public welfare, and tend to mutual strength and advantage; to improve the science and art of pharmacy, by diffusing scientific knowledge among apothecaries and druggists, fostering pharmaceutical literature, developing talent, stimulating discovery and invention, and encouraging home production and manufacture; to regulate the system of apprenticeship and employment, so as to prevent, as far as practicable, the evils flowing from deficient training in the responsible duties of preparing, dispensing, and selling medicines; to suppress empiricism, and to restrict the dispensing and sale of medicines to regularly educated druggists and apothecaries, etc. Pharmacists and druggists in good standing, and teachers of pharmacy, chemistry, and botany, who may be especially interested in pharmacy and materia medica, are eligible to membership. A handsome volume of transactions is annually issued: the proceedings being faithfully recorded by the official phonographic reporter of the Association.

This body has undoubtedly given a great stimulus to the onward progress of pharmacy. Previous to 1851, there were only three teaching schools of pharmacy in existence in this country. Now there are more than a dozen, with a total of six or seven hundred students, in addition to numerous pharmaceutical associations in the various States. The national Association has an active membership of about one thousand; but this will probably be annually increased by the addition of several hundred others, as there are from fifteen to twenty thousand persons in the United States who are eligible. The educated German element is a notable feature in these gatherings; and it is assuredly no disparagement to home talent in this direction to repeat the universally recognized fact that this infusion adds depth, force, and steadiness to the labors of the Association. Business is conducted in a somewhat different style from that pursued in the American Medical Association, there being no division into sections, and no

general addresses, and the new President being elected and assuming his duties at an early period of the meeting, instead of at its close. Reports from several standing committees on matters of vital moment are read and discussed, and numerous queries are proposed, to be answered at the next annual meeting. These, and volunteer essays, all of which may provoke an interesting agitation of views, fill up the time of the Association. The amount of actual labor accomplished is enormous, and the representation of earnest, enthusiastic, educated workers is proportionally greater, I am disposed to think, than conventions usually offer. From a general glance at the calibre of this representative body, I would cordially subscribe to the sentiment expressed by one speaker, that the day has passed when the apothecary is likely to ransack his shelves in a vain effort to fill a prescription for ζ iv of aurora borealis ordered by a quizzical prescriber.

The first general business transacted was the delivery of the address of the retiring President, C. Lewis Diehl, of Louisville, who is also the reporter on the Progress of Pharmacy for the Association. Much of his address was devoted to an appreciative recognition of the labors of the pharmacist and to a brief mention of the assistance which chemistry had lately given him, and a historical sketch of some comparatively recent remedies, as digitalin, jaborandi, and salicylic acid.

The Association keeps a watchful eye lest members may enter it who are not constitutionally qualified; so that when the name of Prof. S. P. Sharples, of Boston, who is Professor in the Dental College, State Assayer, etc., was proposed, it met with slight opposition on merely technical grounds, although in the course of his chemical experience he is frequently called upon to examine and report on pharmaceutical articles.

The officers elected for 1875-6 were the following:

President,—George F. H. Markoe, of Boston.

Vice-Presidents,—Fred. Hoffman, of New York; T. Roberts Baker, of Richmond; C. F. G. Meyer, of St. Louis.

Treasurer,—Charles A. Tufts, of Dover, New Hampshire.

Permanent Secretary,—John M. Maisch, of Philadelphia.

Reporter on the Progress of Pharmacy,—C. Lewis Diehl, of Louisville, Kentucky.

Executive Committee,—George W. Kennedy, Pottsville, Pennsylvania; Joseph L. Lemberger, Lebanon, Pennsylvania; William McIntyre, Philadelphia; Charles A. Heinitsh, Lancaster, Pennsylvania; John M. Maisch, Permanent Secretary, *ex officio*.

Committee on Papers and Queries,—William Saunders, Ontario, Canada; Emil Scheffer, Louisville, Kentucky; James H. Taylor, New York.

Business Committee,—Jacob D. Wells, Cincinnati; Paul Balluff, New York City; William C. Bakes, Philadelphia.

As almost every national representative body of medical, pharmaceutical, and educational interests is to

meet in Philadelphia during the centennial year, it was fair to presume that a favorable opportunity for an international conference of pharmacutists was offered; but the invitation extended by this Association to the Fifth International Pharmaceutical Association, when it recently met at St. Petersburg, was not accepted or refused, but left, as usual, for the Executive Committee of that body to decide, a preference being expressed for London, the meeting possibly not to take place until after a lapse of five years. At the close of that meeting, the members took measures to further the draft prepared by the Paris Pharmaceutical Society, and agreed not to recommend the preparation of extracts by evaporation *in vacuo*; to make a thorough examination into the fluid extracts of the United States Pharmacopœia; and to constitute 59° Fahr. the uniform temperature at which to take the specific gravity of all liquids. The pharmacists of the United States are expected to participate in this enterprise, the progress of which will be watched with much interest by the medical profession.

The Association at Boston would have had a difficult task before it had it attempted, in the report of its Committee on Unofficial Formulæ, to endorse the numerous formulæ which are employed in various parts of this country in the preparation of extracts, elixirs, etc. It was wisely determined that it should be understood that those reported were only collected and printed for general reference; but there is another committee, on elixirs, to whom the portion of the report relating to such preparations was referred, although, in the expressed desire to do away with the whole elixir business, it was doubtless thought that a double-barrelled shot would be twice as effective as one from a single barrel only. The Committee on Elixirs must have been still more puzzled when they had to decide on recommending formulæ for their preparation, for almost every apothecary and every wholesale dealer or manufacturer has numerous specimens of this class of elegant preparations to which he prefixes his own name as distinctive and separate elixirs from all others advertised by rival pharmacutists. It was suggested that some clue to their composition should always be given in the name adopted, and also that a more thorough knowledge of the various syrups, aromatics, spirits, etc., which they contain, would give a more ample field for the choice of auxiliaries, correctives, and vehicles. The importance of co-operation with physicians on these subjects was recognized by several of those who took part in the discussion, for it was deemed absolutely useless to suggest formulæ unless they were to be viewed favorably by medical men, who alone were to prescribe them.

One of the most important reports presented was that on adulterations and sophistications, by the chairman, Dr. W. A. Miller, of Philadelphia. Essential oils are largely adulterated, and many so-called distilled oils are almost absolutely fraudulent. Cases were mentioned where commercial oils, such as those of cedar, spruce, etc., were prepared by placing branches of those trees

in the still, with an amount of turpentine proportioned to the anticipated price which the manufacturer expected to obtain. Europe was catching the contagion of systematic fraud, and processes had been devised there for cheapening all the prominent oils, and an effort was being made to adopt them here. A representative of a foreign house had informed him that all the cheap grades of lavender, rosemary, and red thyme sent to this country by a number of manufacturers contained at least seventy-five per cent. of turpentine. Linseed oil was known to be adulterated with hemp, fish, rosin, and mineral oils; castor oil was found to be composed of lard and croton oil, etc.

Many of the States have adopted pharmacy laws for the protection of the public, by imposing restrictions as to the admission of pharmacutists without sufficient examination, and other measures calculated to improve the tone of the profession. Some of these have been tested before the courts, and their constitutionality sustained. Great annoyance has been caused to druggists by the imposition of a stamp-tax upon the preparations sold by them, but they have been relieved from much of their embarrassment by the construction placed on one of the sections of what is known as the "Little Tariff Bill," by which no tax is imposed on medicinal articles prepared by a manufacturing chemist, pharmacist, or druggist in accordance with a formula published in any standard dispensatory or pharmacopœia in common use by physicians and apothecaries, or in any pharmaceutical journal issued by any incorporated college of pharmacy, when such formula and where found shall be distinctly referred to on the printed label attached to such article, and no proprietary interest is claimed therein; and no stamp is to be required when the formula of any medicinal preparation is printed on the label attached to such article and no proprietorship is claimed.

The desire which authors of valuable papers often experience to give them greater publicity than they receive in the annual volume of the proceedings was partially gratified by the passage of resolutions inviting pharmaceutical and medical journals to publish whatever notes they may desire to make of the proceedings and of the papers presented; and giving their authors the privilege, when they have prepared copies or abstracts of their essays previous to the meeting of the Association, of distributing such copies or abstracts at any time subsequent to the official reading of their papers, the fact being stated at their head that they had been so read.

The manufacturers of gelatin-coated pills must have been seriously discomfited at the results arrived at by Prof. Joseph P. Remington, of Philadelphia, in his examination of the solubility of the various forms of pills kept upon the shelves of the apothecary. We trust that further investigations may be made on the same subject. He found that gelatin-coated pills were the least soluble of the four forms examined, which, expressed in order of greatest solubility, were the simple uncoated pill, the sugar-coated pill, the compressed form, and the gelatin-

coated. It is an undoubted fact that an old sugar-coated pill presents, after the coating has worn away by long keeping, a much moister surface than that offered by a venerable non-coated pill; and that in cases where the sugar-coated pill has been passed through the bowels unchanged by any chemical action in the digestive apparatus—for such cases have been described—some faulty condition has sometimes existed in the individual rather than in the want of power of solution of the pill.

I overheard some amusing instances of physicians' blunders in writing prescriptions detailed in conversation, for such subject seemed to be a fruitful theme of entertainment, each relating his experience in this respect, sometimes in a vein of self-satisfaction that he was able to detect the error. The possibility of mistakes being committed between the passage of a prescription from the hands of the prescriber and into the patient's possession was recognized officially in the Association in a communication from the Philadelphia College of Pharmacy, and in a paper presented by Mr. T. R. Baker, of the Richmond delegation, suggesting proper precautions, and in the passage of a resolution in accordance with a committee report on the subject of maximum doses, authorizing a committee of conference with the American Medical Association. The medical and pharmaceutical professions of Richmond were to consult together "on the importance of writing prescriptions in a legible hand, without erasures or interlineations; of using the technical language and abbreviations of the Pharmacopœia and the U. S. Dispensatory; of writing directions for use and dose as a guide to the dispenser in case of error in quantity of any active ingredient; also that when an unusual dose of an active and potent medicine is prescribed, the prescriber should affix a caution-mark to inform the dispenser that he is aware that the dose is unusual; that the words *not renewable* should be added in appropriate cases; and that the sale of opium and its preparations, chloral, etc., should be stopped, unless sold on competent medical authority."

One of the most interesting features of these gatherings is the elaborate report presented by C. Lewis Diehl, of Louisville, on the progress of pharmacy. To be sure, it is too lengthy to be read in full at the annual meeting, for in the completeness and intrinsic value of its researches it rivals the best productions on similar subjects that emanate from the most indefatigable of European workers and writers; but the members are able at their leisure, and to their great instruction, to peruse in the annual volume the great mass of facts he has collected in the several hundred pages occupied by him. He purposely avoided more than a passing allusion to points of therapeutic value associated with the various subjects, and, in the different sections into which his report is divided, considered the progress during the year of pharmacy; materia medica, giving such information as has been obtained in regard to the history of crude drugs and their botanical characteristics; inorganic chemistry, with the results of investigations of inorganic substances; organic chemistry, and a review

of the works relating to these subjects during the year.

It was rather a humiliating confession that Prof. John M. Maisch had to make in his remarks on the sale of patent medicines, that, in spite of the professed opposition of the Association to this traffic, the sale must go on because the public called for them. This was doubtless founded on the view that some one must sell them, and why should we (the apothecaries) not derive the profit from their sale? It will always be a stumbling-block in their path of progress, however, that they must continue to sell these numerous specimens of quackery, of whose composition they are usually ignorant, and thus sacrifice principle to the demands of trade. They took somewhat of a middle course, however, by agitating the dissemination of some form of health-almanac, similar to those published by proprietors of patent medicines, containing analyses of these compounds when such could be obtained. But in the mean while they will continue to sell them.

The unwarranted sale of diplomas without attendance on lectures has been so fruitful a source of evil in the medical profession that we are not surprised to see our pharmaceutical friends boldly grappling with it on the first occasion that offers. It appears that some one who wished the degree wrote to the Tennessee College of Pharmacy, and received a letter from the Secretary and acting Treasurer of that institution, offering to examine and graduate him without attending the lectures. On motion of Prof. Bedford, of New York, a resolution was passed inquiring whether such action was authorized by the College or was only the act of the officer referred to. It seems that while other colleges confer the degree of Graduate in Pharmacy, this Western institution claims that it confers a still higher degree when it bestows that of Doctor of Pharmacy. By the most reliable pharmacutists this is considered an unnecessary degree, inasmuch as the other is in itself sufficient, and the title of doctor opens the way for the practice of medicine by the apothecary, the public being very readily deceived by that prefix. The Secretary of the Tennessee College was present, and boldly claimed a higher rank for that institution on account of its advanced degree, and explained the meaning of his letter to be an expressed willingness to confer the title of doctor on graduates of other institutions without requiring attendance on all the lectures. We hope, for the honor of the Association, that this matter will be thoroughly sifted.

I wish it were in my power to give you an abstract of the large number of valuable essays presented, and the discussions which followed. There was hardly one of these contributions to pharmaceutical literature that did not give evidence of good work and practical progress in the advance of pharmacy. Under such investigations the physician will be constantly benefited by having placed in his grasp the results of improved processes of manufacture of remedies. Quite a number of essays, for instance, were read on phosphorus and its forms of administration, new methods of preparing phosphoric acid, etc. The antiseptic properties of chloral were

corroborated in a paper on the subject by Mr. T. R. Baker, of Virginia. Pancreatin was said, in an essay by Prof. Emil Scheffer, of Louisville, to be destroyed when taken into the stomach, and it, therefore, in his view, could have neither physiological nor therapeutic effect when administered internally. Mr. Charles Bullock, of Philadelphia, read an essay of great practical moment on the preparation of the bromides of the organic and inorganic bases used in American pharmacy. Prof. Sharples urged the importance of adopting the metric system of weights and measures, to save all the trouble the pharmacist now has in mixing by one scale and selling by another.

The members of the Association were very bounteously entertained by their Boston friends. This body will hold its next session in Philadelphia on the second Tuesday of September, 1876. In connection with the meeting at Boston, a very elaborate exhibition was made of all kinds of pharmaceuticals, chemicals, druggists' sundries, rubber goods, etc., etc. I understand that one of our Philadelphia manufacturers was insured for twenty thousand dollars' worth of articles exhibited; while a case of ambergris which, to the uninitiated, appeared an unpretending display, was said to be valued at fifteen thousand dollars. The Massachusetts College of Pharmacy was the recipient of a rare and valuable collection of crude drugs from a New York firm, each bottle being labelled with its scientific and common name, the part used, the botanical source, and locality where produced; and also of a herbarium containing over three hundred specimens, collected by Prof. Gunther of the University of Jena.

R. J. D.

REVIEWS AND BOOK NOTICES.

THE DISEASES OF THE HEART AND OF THE AORTA.
By THOMAS HAYDEN, Fellow of the King and Queen's College of Physicians. Lindsay & Blakiston, Philadelphia, 1875.

This handsomely-printed work is apparently composed of imported sheets, bound so as to form two volumes of over six hundred pages each, although numbered consecutively from 1 to 1232. The author evidently has had a very wide and well-used experience in that of which he writes, is well versed in modern physiology and pathology, and holds a fluent pen. Consequently, the book is an excellent one, and, as the teachings of the text are abundantly illustrated by the reports of about one hundred and fifty cases, Dr. Hayden's effort will probably attain the popularity it deserves. Personally, we confess to a preference for what may be considered the hammered style of writing, in which everything is as condensed as possible: therefore the treatise of Walshe in our library shall stand above that of Hayden. But to the large class who prefer less of strength and conciseness, and more of elegance and fluency, we can heartily commend the volumes before us. The chief and indeed the only complaint we have to make is, the apparent ignorance of the author of the German tongue and of much of the treasures that lie hidden beneath its barbarisms. For this almost national fault he makes what amend is possible by a thorough acquaintance with the literature of Eng-

land, America, and seemingly also of France. We think, however, that if he were better acquainted with the German writers he would concerning certain matters not purely clinical have adopted a rather different tone. As an example, we may cite the muscular degenerations of typhus and other fevers originally discovered by Zenker, which Dr. Hayden, by inference, would lead one to believe existed rather in the brain of the observer than in the muscles of his subjects. We do not mean, however, to disparage the treatise in hand: concerning all clinical matters Dr. Hayden writes like one who speaks with the authority of personal knowledge, and the book must prove a useful one.

TRANSACTIONS OF THE COLLEGE OF PHYSICIANS.
Third Series, Vol. I.

This is really the eighth volume of Transactions which our College of Physicians has published, and, as the product of the work of a single year, it is a very creditable as it is a very valuable volume, which is composed of a series of papers that have already appeared in the columns of this journal, either as abstracts or in full. It is evident that any further notice of these papers would be superfluous, and we leave them with the remark that nearly all of them are of the highest character, and that one or two of them must achieve a place among the medical classics of the language,—papers which physicians a hundred years from now will go back to, precisely as we now refer to some of the original productions of Hunter, Abercrombie, and others. We wish the College all success in its new undertaking, and express the hope that it may long retain, as it has ever held, the foremost position among the most influential and productive medical societies in the United States.

GLEANINGS FROM OUR EXCHANGES.

IVY-POISONING (*The Boston Medical and Surgical Journal*, September 2, 1875).—Dr. James C. White describes the effect of the poison of rhus, and cautions those who are unacquainted with the plant to avoid any vine or bush growing by rocks, fences, and woodsides and having glossy leaves arranged in threes. He says there is no danger of contagion by contact with the eruption upon another person. In regard to treatment, as the poison is a volatile acid, an alkali would therefore suggest itself as the most fit agent to counteract its action. Thorough washing of the parts, as soon as possible after contact with the poison, in cooking-soda or saleratus-water, or in strong soap-suds, especially those of soft soap, which contains an excess of alkali, is therefore the best primary treatment. When these or other alkaline preparations are not to be obtained, an abundance of water alone should be used, as soon as possible. After absorption has taken place or the eruption has begun to show itself, less benefit is to be expected from such applications alone. Remedies are then to be used which will best control and shorten the inflammatory process in the tissues of the skin,—those, in fact, which are found to be most efficacious in corresponding stages of acute eczema. Among these are some which have a special reputation, as solutions of acetate of lead or sulphate of copper, applied frequently as a wash. Perhaps nothing is better than common black wash used as an evaporating lotion for half an hour at a time, twice daily, the lime-water acting also as a chemical antidote, if possibly such action is still in season at this later stage. In the intervals between the applications of these washes the parts may be kept covered with cold-water dressings, with plasters of diachylon ointment, or with a powder of starch and oxide of zinc, according to the

rules familiar to physicians for the treatment of acute eczema. By these means the process is checked and shortened, and the sufferings of the patient are greatly alleviated.

CARCINOMA (*New York Medical Journal*, September, 1875; *von Med.-Chir. Centralblatt*, 20, 1875).—Prof. Von Nussbaum, after treating over one thousand cases of cancerous disease, has arrived at the following conclusions:

1. Cancer is a proliferation of the epithelium, which progresses rapidly, and crowds out the connective-tissue stroma, undergoes ulceration from slight causes, determines local destruction, induces severe general illness from hemorrhages and discharges, and finally disseminates its particles throughout the whole body, and generates an identical proliferation and destruction in various organs, and thus destroys life.

2. Its causes are found in advanced age, grief and care, and when there is a disproportion between epithelium and connective tissue,—warts, cicatrices, glandular swellings, etc.; and, lastly, those tissues are more especially affected which are subjected to frequent irritation, though not placed in a condition of acute inflammation. Cancer is not congenital or contagious. At first it is a purely local disease, which only becomes a dyscrasia by the dissemination of its elements throughout the body.

3. The humoral infection must be distinguished from the dyscrasia. The former can disappear entirely, and never contra-indicates the operation.

4. Recurrence of cancer is either continuous, when cancerous elements have remained, or regionary, when neighboring tissue disposed to cancerous disease has remained; or it may be a recurrence by transplantation, when cancerous particles have been disseminated by passing into the circulation through opened vessels.

5. Cancer can be cured radically by early and extensive operation.

6. Exact and extensive statistics show that patients who are operated upon live longer than those who refuse all interference.

7. In the treatment, all remedies which act on the tissues, blood, and nerves, come into consideration. Early and extensive operation ranks first. Caustics are often useful, especially after the cancer has been scooped out. Parenchymatous injections deserve trial.

A NEW INSTRUMENT IN THE OPERATION FOR VESICO-VAGINAL FISTULA (*New York Medical Journal*, September, 1875).—Dr. William A. Byrd, having had trouble, in some cases of vesico-vaginal fistula, to distinguish the red and protruding wall of the bladder from the surrounding tissues, has employed the following method of overcoming the difficulty. He takes two ordinary toy rubber balloons, slips one inside of the other so as to gain additional strength, and fastens their necks over a piece of elastic tubing. At the time of the operation a wire is passed into the bladder through the urethra and out through the fistula into the vagina, the end being bent back so as to protrude from the vulva. It is then attached to the flexible tube fastened to the balloon, and is made to retrace its course, bringing the end of the tube out of the meatus urinarius, and leaving the balloon in the bladder. The wire is then detached, the nozzle of a syringe inserted in the tube, and the balloon slowly filled with water. Dr. Byrd claims the following advantages for this instrument. 1. The material is inexpensive, and the apparatus can be easily made in a short time. 2. It is easily dilated with any ordinary syringe, when it defines the fistula perfectly, throwing the walls of the fistula prominently out from the convex surface of the balloon, which renders the paring more speedy, certain, and easy. 3. It prevents the posterior wall of the bladder from interfering with the

operation. 4. It prevents blood flowing into the bladder and there clotting and giving trouble. 5. It allows the sutures to be more rapidly inserted, and more easily placed at proper distances from each other. 6. By pressure and the temperature of the distending fluid, it represses hemorrhage. 7. When undistended it occupies a very small space. 8. It can readily be applied as a tampon in cases of metrorrhagia.

ANÆMIA (*The Lancet*, August 7, 1875).—Dr. Julius Pollock calls attention to that form of anæmia which is met with in young unmarried women and is usually associated with some disorder of the catamenial function. He relies chiefly upon steel to effect a cure; but if the tongue is coated and the digestion much impaired, the more astringent forms of iron, such as the sulphate or the perchloride, are often not tolerated at first; and the ammonio-citrate, the *mistura ferri comp.*, or the *ferrum redactum*, will be the best to begin with. In a large number of cases he has found nothing so successful as a combination of the ammonio-citrate of iron and rhubarb in suitable doses, with equal parts of some bitter infusion and peppermint-water. Sometimes the addition of two or three grains of the carbonate of ammonium seems to be useful. He makes rather a point of the rhubarb, although it is so disagreeable to take, believing it to assist the action of the steel, especially when the stomach is out of order. If the patient is very nervous, ten grains of the bromide of potassium may be added with advantage to each dose of the mixture. If the rhubarb in the mixture does not act enough upon the bowels, it will be necessary to prescribe some aperient pill to be taken at bedtime. Preparations containing aloes are of service, and may be combined with steel. Pepsine is often useful with the meals. The diet should be light and simple; beer had better be avoided in most cases, and a glass or two of light claret may take its place with advantage. Claret is certainly better than port, although that wine is so often recommended. A moderate amount of exercise out of doors, when the weather permits, should be insisted upon, but anything like fatigue must be avoided. A tepid bath in the morning and a rub down afterwards with a rough towel is a good thing. In a few weeks, more or less, the steel and rhubarb mixture may be left off, and fifteen drops of the solution of perchloride of iron given after each meal in a wineglass of water.

AN IMPROVED METHOD OF OBTAINING SUPPORT FOR FRACTURED BONES OF THE EXTREMITIES (*New York Medical Journal*, September, 1875).—Dr. S. Wackerhagen uses the following method in treating fractures of the long bones:

After replacing the fragments as accurately as possible (extension being maintained by assistants), the limb is smoothly bandaged with cotton wadding, prepared in the form of an ordinary roller; a flannel bandage spread with dry plaster of Paris, and rolled, is now soaked in warm water (to which are generally added about two fluidounces of saturated solution of sulphate of potassium), and applied to the limb, over the wadding, by circular and reversed turns. One layer of the flannel applied in this way is amply sufficient for support.

When we wish to inspect the point of fracture, the dressing, which is only about an eighth of an inch thick, is easily cut through by a pair of curved scissors.

If it be desired to employ lateral splints, the dressing should be cut in the median line of the anterior and posterior surfaces. If antero-posterior support is preferred, it should be cut through the lateral surfaces. The splints should now be varnished on their inner and outer surfaces with shellac, or this preparation may be applied to the outer surface before removal.

The shellac seems to permeate the dressing sufficiently

to increase the strength of the splint, and at the same time renders it slightly flexible instead of brittle, as is the case when plaster of Paris is used alone.

CASE OF TRANSFUSION IN DIABETES MELLITUS (*The Cincinnati Lancet and Observer*, September, 1875).

—Dr. C. Shriver reports the case of a man, æt. 48, who had been affected for four years with diabetes, and who had become greatly emaciated and very weak. All the usual remedies had failed entirely, when it was determined to try transfusion. This was performed by the direct method, about twenty-five ounces of blood from the common carotid artery of a three-months-old lamb being thrown into the median basilic vein of the patient. The phenomena observed during the transfusion were oppression of the chest, irregularity and quickening of the heart's action, cough, vertigo, perspiration, and intense pain across the lumbar region, disappearing in a few minutes. The results were much more favorable than were expected. He has nearly regained his health, has a good appetite, sleeps well, only rises at night once instead of ten or twelve times to urinate, and is apparently on the road to complete recovery.

GALLIC ACID IN ALBUMINURIA FOLLOWING SCARLATINA (*The American Practitioner*, August, 1875).—Dr.

J. T. Jameson reports two cases of albuminuria occurring as a sequel of scarlet fever, and in which he employed gallic acid with marked success. In one case, a child æt. 6 years caught cold during convalescence, and a day or two after the face became oedematous; there was pain in the head, and slight fever; the urine was quite bloody, and on testing in the usual manner presented considerable coagulation. The patient was put upon a saturated solution of gallic acid, a teaspoonful every two hours. In seven days the urine was free from albumen and copious in quantity, and the child seemed well, with the exception of debility, for which the muriated tincture of iron was prescribed. About ten days after this, in consequence of fresh exposure to cold, there was a slight relapse, the urine becoming again bloody and the face puffed; but on resuming the gallic acid for a few days these symptoms speedily subsided, and the recovery became permanent. In this case the gallic acid was administered unaccompanied by any other medicine, except an occasional dose of castor oil to regulate the action of the bowels.

CATHETERISM IN LACERATION OF THE URETHRA (*The Lancet*, August 21, 1875).—Mr. Teevan reports two cases

of retention of urine from laceration of the urethra, and remarks that if a laceration or false passage existed in the floor of the deep portion of the urethra, a curved metal catheter ought to be passed, as it could be made to hug the roof of the urethra, and so avoid slipping into the *cul-de-sac* in the floor. If, on the contrary, the laceration were in the roof, a straight elastic catheter ought to be introduced, as it always tended, when passed, to keep to the floor of the urethra, and would thus escape becoming locked in any rent in the roof of the canal.

MISCELLANY.

AMERICAN DENTISTRY IN 1796.—The following is a copy of an advertisement issued in 1796 by one Josiah Flagg, surgeon dentist, who

"Informs the public that he practices in all the branches with improvements, [i. e.] Transplants both live and dead Teeth with great conveniency, and gives less pain than heretofore practiced in Europe or Amer-

ica: . . . Sews up Hare Lips: . . . Cures Ulcers: . . . Extracts Teeth and stumps or roots with ease: . . . Reinstates Teeth and gums that are much depreciated by nature, carelessness, acids, or corroding medicine: . . . Fastens those Teeth that are loose (unless wasted at the roots); regulates Teeth from their first cutting to prevent fevers and pain in children; assists nature in the extension of the jaws, for the beautiful arrangement of the second Set, and preserves them in their natural whiteness entirely free from all scorbutic complaints. And when thus put in order and his directions followed (which are simple), he engages that the further care of a *Dentist* will be wholly unnecessary; . . . Eases pain in teeth without drawing; . . . Stops bleeding in the gums, jaws, or arteries; . . . Lines and plums Teeth with virgin Gold, Foil or Leads; . . . Fixes *gold Roofs and Palates* and artificial Teeth of any quality, without injury to and independent of the natural ones, greatly assisting the pronunciation and the swallow when injured by natural or other defects. A room for the practice with every accommodation at his house, where may be had Dentifrices, Tinctures, Teeth and Gum Brushes, Mastics, &c., warranted approved and adapted to the various ages and circumstances; . . . also Chew-sticks, particularly useful in cleansing the fore Teeth and preserving a natural and beautiful whiteness; which Medicine and Chew-sticks are to be sold wholesale and retail, that they may be more extensively useful.

"* * Dr. Flagg has a method to furnish those Ladies and gentlemen or children with Artificial Teeth, Gold Gums, Roofs, or Palates, that are at a distance and cannot attend him personally.

Cash Given

for Handsome and Healthy Live Teeth
at No. 47, Newbury-Street, Boston (1796)."

The document is ornamented in one corner by very formidable and antiquated instruments, while in the other are to be seen tooth-brushes quite of the modern pattern. It has been preserved by a descendant of one who, as may be seen on the back, purchased a brush and tincture from Josiah Flagg in the year 1800.—*Boston Medical and Surgical Journal*.

THE FEAT OF CAPTAIN WEBB, which has been so fully reported in the secular press, is certainly one of the most remarkable instances of physical endurance, if not the most remarkable, on record. In a recent number of *The Lancet* (September 4), his brother, Mr. Thomas Low Webb, M.R.C.S., gives the following report as to his condition on leaving the water:

"He assures me that on landing he did not feel at all cold, but was as warm as when he started. He felt, however, fearfully tired and exhausted, and was very sleepy. He fell asleep several times as he was being driven to his hotel, though roused repeatedly by his cousin (Mr. G. H. Ward, who never left him throughout), who thought it best not to let him sleep until he had taken some nourishment. At the Hôtel de Paris, he went to bed, and drank some hot wine. Immediately on getting to bed he took his own temperature with a thermometer with which I had provided him,

and found it to be exactly 98° Fahr. He did not count his pulse, but *felt* it, and says it was 'slower than usual.' After five hours or so of sleep, he awoke feeling rather hot and feverish. He then took his temperature again, when it had risen to 101° Fahr. He says that his face was then flushed, and his skin hot and dry. He then slept again for some time, and on waking felt himself 'all right,' excepting a troublesome stiffness of the arms and legs, scarcely to be wondered at.

"Towards the termination of his swim he became nearly blind from the salt water. At present he is perfectly well in every respect,—indeed, as well as ever he was; for we must not consider the abrasions on his neck caused by the salt water to be of any account. That he is apparently *not one whit the worse* is an immense relief and satisfaction to me, and a further proof of the perfection and soundness of his circulatory system and constitution generally."

NOTES AND QUERIES.

WINONA, MINN., Sept. 15, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

I transmit herewith a slip from the *Chicago Times* (daily), September 14, 1875, to show one of the many ways by which "quacks" are made M.D.'s nowadays.

Very respectfully yours,

FERDINAND LESSING, M.D.

FOR SALE.—A physician (regular) leaving practice, will sell his diploma. Address O, TIMES office.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY FROM SEPTEMBER 13, 1875, TO SEPTEMBER 20, 1875, INCLUSIVE.

MILHAU, J. J., SURGEON.—Relieved from duty at Fort Columbus, New York Harbor, and granted leave of absence for six months. S. O. 183, c. s., A. G. O., September 11, 1875.

SMITH, A. K., SURGEON.—Relieved from duty in Department of the Missouri, and assigned to duty at Fort Columbus, New York Harbor. S. O. 183, c. s., A. G. O., September 11, 1875.

HEGER, ANTHONY, SURGEON.—Relieved from duty in Department of Dakota, and assigned to duty at Willett's Point, New York Harbor. S. O. 182, c. s., September 9, 1875.

HEGER, ANTHONY, SURGEON.—By S. O. 177, Headquarters Department of Dakota, September 13, 1875, upon being relieved from duty by Surgeon Byrne, will comply with requirements of S. O. 182, from War Department, relieving him from duty in Department of Dakota.

BYRNE, C. C., SURGEON.—By S. O. 177, Headquarters Department of Dakota, September 13, 1875, relieved from duty at Fort A. Lincoln, D. T., and assigned to duty at Fort Snelling, Minn., relieving Surgeon Heger, U.S.A.

BROOKE, JOHN, ASSISTANT-SURGEON.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 182, c. s., A. G. O., September 9, 1875.

BROOKE, JOHN, ASSISTANT-SURGEON.—By S. O. 132, Headquarters Department of the South, September 13, 1875, to report to the Commanding Officer, Raleigh, N. C., for duty at that post.

MONROE, F. LEB., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, to report to the President Army Medical Board, for examination for promotion, and, upon its completion, to the Commanding General, Department of Dakota, for assignment to duty. S. O. 182, c. s., A. G. O., September 9, 1875.

BYRNE, C. B., ASSISTANT-SURGEON.—Relieved from duty at Willett's Point, New York Harbor, to report to the President Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of Texas, for assignment to duty. S. O. 182, c. s., A. G. O., September 9, 1875.

HARVEY, F. F., ASSISTANT-SURGEON.—By S. O. 182, Headquarters Military Division of the Atlantic, September 13, 1875, granted leave of absence for one month, on surgeon's certificate of disability.
